Introduction

Materials containing boron investigated for solid state neutron detection [1] include semiconducting boron carbide [1–12], boron nitride [13–15], boron phosphide [16–19], Mg₂B₁₄ [20] and lithium borates [21–27]. In particular, undoped lithium tetraborate (Li₂B₄O₇) is capable of being enriched with ⁶Li up to 95% and ¹⁰B up to 97.3% [26], well above the natural abundances (⁶Li-7.42%, ¹⁰B-19%), thereby increasing thermal neutron capture [1, 21, 26].

Many rare earth (RE) ions exhibit high luminescence efficiency in host borate crystals and glasses with various chemical compositions [27–46]. Consequently, combining rare earth dopants with the high thermal neutron capture cross-sections of ⁶Li and ¹⁰B may result in highly efficient neutron scintillators [26, 27, 46, 47]. In lithium tetraborate, this is particularly true as undoped Li₂B₄O₇ has a wide band gap of ~9.8 eV, based on measurements of {100} and {110} oriented single crystals [24, 48–51] and is highly transparent in the visible spectrum. In general, the borates, including lithium tetraborate (Li₂B₄O₇) single crystals, are characterized by high optical transmission from far infrared to vacuum ultraviolet [49, 52].

Obtaining single crystal Li₂B₄O₇ is technologically challenging; thus, application to large area scintillation detectors will favor glasses over single crystals due to lower fabrication costs. The very low crystal growth velocity and high melt viscosity lead to difficulties with dopants, particularly rare earths [53, 54]. Therefore, from the technological viewpoint, the vitreous Li₂B₄O₇ compounds are more advantageous when compared with their crystalline analogs.

Padlyak, Teslyuk and coworkers studied the luminescence properties of some rare earth doped lithium tetraborate (Li₂B₄O₇:RE) glasses [39, 41]. They deduced from the optical characteristics that the rare earths generally occupy the Li⁺ site exclusively in the +3 valence state. Compared to other rare earth doped borates and crystalline counterparts, a broadening of the spectral lines was observed which was theorized to be a result of the dopant interaction with a varying O-coordination environment in the glassy material.

In this research, lithium tetraborate glasses have been separately doped with four different rare earth elements: Nd, Gd, Dy, and Er. The local environment about the dopants was studied with EXAFS in order to determine the positional disorder of the varying O environment, an average coordination number and bond length, and to assist in validating the presumption that a varying O-environment is the source of the spectral line broadening. Further, the experimentally determined site has been used as a basis for density functional theory (DFT) calculations to investigate the electronic nature of the hybridization in lithium tetra-

The four dopants (Nd, Gd, Dy, and Er) substitutionally occupy the Li⁺ sites in lithium tetraborate (Li₂B₄O₇:RE) glasses as determined by analysis of the extended X-ray absorption fine structure. The dopants are coordinated by 6-8 oxygen at a distance of 2.3 to 2.5 Å, depending on the rare earth. The inverse relationship between the RE-O coordination distance and rare earth (RE) atomic number is consistent with the expected lanthanide atomic radial contraction with increased atomic number. Through analysis of the X-ray absorption near edge structure, the rare earth dopants adopt the RE³⁺ valence state. There are indications of strong rare earth 5d hybridization with the trigonal and tetrahedral formations of BO₃ and BO₄ based on the determination of the rare earth substitutional Li⁺ site occupancy from the X-ray absorption near edge structure data. The local oxygen disorder around the RE³⁺ luminescence centers evident in the structural determination of the various glasses, and the hybridization of the RE³⁺ dopants with the host may contribute to the asymmetry evident in the luminescence emission spectral lines. The luminescence emission spectra are indeed characteristic of the expected f-to-f transitions; however, there is an observed asymmetry in some emission lines.
behind the spectral line broadening observed in the emission spectra.

**MATERIALS AND METHODS**

The doped Li₂B₄O₇:Nd, Li₂B₄O₇:Gd, Li₂B₄O₇:Dy, and Li₂B₄O₇:Er glasses were obtained in the air from corresponding polycrystalline compounds according to standard glass synthesis. For solid state synthesis of the doped materials, highly pure carbonate (Li₂CO₃) and boric acid (H₃BO₃) were used. Solid-state synthesis of the doped Li₂B₄O₇:RE compounds was carried out using a multi-step heating process that follows the reaction sequence [39, 41]:

\[
\begin{align*}
\text{Li}_2\text{CO}_3 + \text{H}_3\text{BO}_3 (150^\circ\text{C}, \text{H}_2\text{O} \uparrow) & \rightarrow \text{Li}_2\text{CO}_3 + \alpha - \text{HBO}_2 (250^\circ\text{C}, \text{H}_2\text{O} \uparrow) \\
& \rightarrow \text{Li}_2\text{CO}_3 + \beta\text{O}_3 (600^\circ\text{C}, \text{H}_2\text{O} \uparrow) \\
& \rightarrow \text{Li}_2\text{B}_4\text{O}_7 + [\text{Li}_2\text{CO}_3 + \beta\text{O}_3] \\
& \rightarrow (800^\circ\text{C}, \text{H}_2\text{O} \uparrow) & \rightarrow \\
& \rightarrow \text{Li}_2\text{B}_4\text{O}_7
\end{align*}
\]

The Nd, Gd, Dy, and Er impurities were added as RE₂O₃ (RE= Nd, Gd, Dy, and Er) in amounts of 0.5 and 1.0 mol. %. Large doped glasses were obtained by fast cooling of the corresponding melt that was heated more than 100 K higher than the melting temperature for excluding the crystallization processes. Samples were cut for optical measurements and polished to a size of approximately 5 × 3 × 2 mm³.

Optical absorption spectra were recorded at room temperature with a Varian spectrophotometer (model 5E UV–VIS–NIR). Emission and luminescence excitation spectra were acquired with a photomultiplier and an InGaAs detector.

**OPTICAL ABSORPTION AND LUMINESCENCE**

High-quality scintillation is dependent upon significant quantum efficiency while retaining optical transparency [27, 43–47]. For energies less than 3.3 eV (wave lengths longer than 375 nm) the absorption is low [26, 27, 49, 70, 71] and the optical absorption spectra of the investigated glasses are dominated by absorption bands of the Nd³⁺, Gd³⁺, Dy³⁺, and Er³⁺ centers and can be generally assigned to the appropriate electronic f to f transitions, as illustrated for the doped Li₂B₄O₇:Nd glass in Figure 2.

Although the luminescence emission spectra are characteristic of the f to f transitions of the +3 rare earth ions, the effect of the host matrix plays a role. In the case of the Nd³⁺ centers, where four characteristic f to f transition bands due to the ⁴F₃/₂ → ⁴I₈/₂, ⁴F₃/₂ → ⁴I₁₁/₂, ⁴F₅/₂ → ⁴I₁₃/₂, and the ⁴F₃/₂ → ⁴I₁₅/₂

![FIGURE 1 | The undoped lithium tetraborate unit cell. The 104-atom-unit cell consists of bridging BO₃ and BO₄ complexes [63, 64], with Li⁺ ions distributed throughout.](Image 312x561 to 539x712)
dipole transitions (some shown in Figure 3) combine to provide a net quantum efficiency of 24%, inhomogeneous broadening of spectral lines does occur [72, 73]. We know that the rare earth states will couple to the host matrix, as clearly demonstrated for rare earth doped GaN [74]. As with prior studies [41], the rare earth ions are placed in the Li⁺ site but there is positional disorder of the RE³⁺ luminescence centers in the Li⁺ sites of the Li₂B₂O₇ lattice and this is characterized by slightly different spectroscopic parameters compared to other rare earth doped borates and crystalline counterparts. EXAFS studies of the L3 edge indicate that the local structure (first coordination shell) around the rare earth ions in glassy lithium tetraborate samples is closely similar. This similar result was observed in the EXAFS study of rare earth impurities on crystal and glass samples of the CaO–Ga₂O₃–GeO₂ system [75]. The structural studies must be understood in this context.

EXTENDED X-RAY ABSORPTION FINE STRUCTURE

In Figure 4, the normalized experimental XAFS signal is plotted for Li₂B₂O₇:Nd. All the rare earth doped samples of this study, Li₂B₂O₇:Nd, Li₂B₂O₇:Gd, Li₂B₂O₇:Dy, and Li₂B₂O₇:Er, have very similar XAFS spectra (Figure 4 inset), including the presence of the sharp white line: a strong feature just above the absorption edge. The measured L3 edge for the Li₂B₂O₇:Nd was determined to be 6212 eV by identifying the inflection point on the rising photoelectric edge, or about 4 eV greater than the expected 6208 eV [60]. This shift in the dopant core level absorption edge is typical of lithium tetraborate and in some cases has been attributed to the large band gap of this oxide, even when doped [66] (although such a shift is commonly related to the charge on the absorbing element – a rare earth in this case). This shift in the L3 absorption edge is similar for all the data obtained for all four of the rare earth doped Li₂B₂O₇ glass samples.

In Figure 5, the experimental EXAFS spectra have been extracted from the data in Figure 4, taken above the rare earth dopant L3 edge, have been replotted as a function of wave vector k for the Li₂B₂O₇:Nd, Li₂B₂O₇:Gd, Li₂B₂O₇:Dy, and Li₂B₂O₇:Er glass samples. In all cases, the EXAFS is evident up to approximately 6 Å⁻¹ and is similar for the rare earth doped lithium tetraborate samples studied, with only small shifts. The signal-to-noise in the EXAFS spectra deteriorate with wave vectors greater than about 7.5 Å⁻¹ as is expected for glassy samples when the host matrix about the dopant consists primarily of low Z material [55, 67]. The energy range available for the various EXAFS spectra is limited by the presence of the L2 edge; hence, higher Z elements have a wider EXAFS energy range.

The rare earth doped lithium tetraborates are very similar in structure, as is evident from the EXAFS spectra in Figure 5. The
similarity in the EXAFS features for all the samples is an indication that the rare earths dope the Li$_2$B$_4$O$_7$ lattice in a similar fashion. This is expected, as nearly all lanthanides adopt the +3 valence state [27–47]. In spite of the similarities of the spectra obtained for the Li$_2$B$_4$O$_7$:Nd, Li$_2$B$_4$O$_7$:Gd, Li$_2$B$_4$O$_7$:Dy, and Li$_2$B$_4$O$_7$:Er glass samples, there are small shifts in wave vector placement of the EXAFS oscillations with increasing atomic number. This characteristic shift in the EXAFS features corresponds to smaller bond lengths with increasing atomic number (lanthanide contraction); larger wave vector components correspond to smaller bond lengths in the Fourier transformation to $R$-space.

The reliability of the structural information from our EXAFS data is limited in scope to the first coordination shell due to the signal-to-noise deterioration. Furthermore, the structural information is an indication of the average environment due to the signal-to-noise deterioration. The Fourier transformed EXAFS spectrum for Li$_2$B$_4$O$_7$:Nd is plotted in Figure 6. The Fourier transformed EXAFS is typical for all the rare earth doped glass samples studied: Li$_2$B$_4$O$_7$:Nd, Li$_2$B$_4$O$_7$:Gd, Li$_2$B$_4$O$_7$:Dy, and Li$_2$B$_4$O$_7$:Er. The out-of-phase real and imaginary components for Nd, Gd, Dy, and Er are shown. There is a trend from left to right in the inset, with the left most (small dash) line resulting from the Er doped sample and then as the atomic number decreases the peak position moves to longer bond length (Er → Dy → Gd → Nd) with Nd as the right most (solid) line.

Due to the size and oxygen coordination number of the rare earths, placement of a rare earth dopant in the B complexes can almost immediately be excluded. A rare earth substitution for the B atom sites would result in a very large distortion of the lithium tetraborate lattice that does not fit with our experimental EXAFS data. Table 1 supports our position as to why a rare earth in a B substitution site can be neglected. To have a rare earth substitute for B in either the BO$_3$ or BO$_4$ clusters would result in coordination numbers of 3 and 4, less than the observed 7–10 oxygen coordination obtained from the EXAFS data. The RE-O bond length is reduced if placed in a boron site, even in the best fit to the EXAFS data. In the case for Nd, the Nd-O bond length is 1.92 Å for a boron site, still significantly less than the 2.7 Å observed, but greatly distort the interlocking BO$_3$-BO$_4$ portions of the unit cell. In general, substituting a rare earth element such as Nd with a radius of roughly 1.123 Å with a coordination number of 6 into
a site where the $B^{3+}$ radius is, on average, 0.15–0.25 Å for oxygen coordination numbers of 3 and 4 respectively, is unphysical. Substituting a rare earth element, such as Nd, in a manner that would in a way that would result in a bond length of 1.273 to 1.373 Å, so as to achieve less distortion of the interlocking BO$_3$-BO$_4$ portions of the unit cell, is possible only if we ignore the obvious problem of coordination number mismatch and the very large resulting charge distributions, as partly elaborated by theory below.

**X-RAY ABSORPTION NEAR EDGE STRUCTURE**

In Figure 8, the experimental X-ray absorption near edge structure (XANES) region for Li$_2$B$_4$O$_7$:Nd has been plotted in more detail than in Figure 4. The solid black line is the experimental data and the dotted red line is the theoretical calculation using FEFF 9.05 and full metal scattering with a cluster size of 5.1 Å and a small convergence factor of 0.05. The Hedin-Lundqvist to ground state exchange correlation was used.

Peak fitting to the XANES data was accomplished by using an arctangent function to represent the bare atom absorption background and two Voigt functions to fit the peaks. The results are listed in Table 2. Two broad peaks are identified in the XANES spectra; one at approximately 4.00 eV beyond the experimentally determined core binding energy (6212 eV) and the other at approximately 37.57 eV above the core L3 edge. A similar peak structure is observed in a rare earth oxygen environment in Joseph et al. [76], where the broad peak at around 35 eV has been associated with nearest neighbor scattering. The other rare earth

doped glass samples Li2B4O7:Gd, Li2B4O7:Dy, and Li2B4O7:Er provide similar results in spite of the differences in the placement of the L3 edge. Additionally, using the Nd doped sample as a reference, the total yields of each of the respective peaks were compared to one another and indicate similar absorption.

If the total area/yield is associated with an unoccupied density of states, then there is no detectable (at least in these sample conditions) difference between the doped samples. In fact, compared to the yield, the first peak has an average ratio of 1.04 and the second 0.99, hovering just around 1 and indicating that the electronic density of states are nearly the same for all of the rare earth doped glass samples. This conclusion is consistent with strong hybridization of the unoccupied rare earth 5d states with the host Li2B4O7 and thus consistent with our model electronic structure calculations discussed below.

For rare earth materials where the rare earth atom is in the +3 valence state, the XANES spectra have a single peak white line, whereas for RE elements that adopt the +4 valence state (e.g., Ce and Pr), the XANES spectra typically have a double peaked white line which occurs due to additional interactions with the ligand environment [77]. In this case, as has been discussed at length in other rare earth dopant systems literature [74, 76–82], the p → s and p → d transitions should be stronger than p → f, although the latter is not strictly forbidden if there is strong 4f state hybridization with the unoccupied band structure [74, 81–83]. In this case, the large white line peak may be associated with 2p → 5d transitions, typical of the +3 rare earth ion and similar to the Eu in doped borate glasses as in Shimizugawa et al. [78]. Placement of a rare earth (e.g., Nd) in a boron site, in the most realistic fit to the EXAFS data (as noted above), presents a huge problem for the XANES data. Such a placement of the rare earth would require an absorption edge shift of about 30 eV instead of the roughly 0 to 3 eV for substitution into a lithium site (Table 1), and it is the latter that is close to the 4 eV absorption edge shift observed, as seen in Figure 4.

DENSITY FUNCTIONAL THEORY STUDIES OF RE DOPED LITHIUM TETRABORATE

To better ascertain the role the host matrix does play in the f to f transitions of the +3 rare earth ions in doped lithium tetraborate, we modeled the electron structure of Li2B4O7 doped with Nd, Gd, Dy, Er and Yb. Our calculations are carried out within density functional theory (DFT) as implemented in the CASTEP software [84]. The plane wave basis set with an energy cutoff around 360 eV, an ultra-soft pseudopotential, and the local density approximation for the generalized gradient approximation (GGA) and Perdew-Burke-Ernzerhof (PBE) exchange and correlation functional are employed [85]. The DFT+U method was used for the corrections of on-site Coulomb interactions with U = 6 eV. These computational conditions were previously found to be successful with rare earth doped GaN studies [74]. In addition, we utilize the ensemble density functional theory (EDFT) [86, 87] scheme in CASTEP to overcome the convergence problem inherited in the RE system. In the Da Silva et al. [88], density functional theory calculations for CeO2 and Ce2O3 found that Perdew-Burke-Ernzerhof plus a scalar Hubbard U approach (PBE+U) worked reasonably well, with results similar to the Heyd-Scuseria-Ernzerhof hybrid functional (HSE). For example, PBE+U and HSE predict CeO2 to be an insulator with the band gaps 5.3 and 7.0 eV respectively compared to the experimental value of 6.0 eV. The calculated energy difference between the lowest 4f state and the vacant conduction band (Eg-4f) of Ce2O3 were found to be 2.6 eV (PBE+U) and 2.5 eV (HSE) compared to the experimental value of 2.4 eV [88]. Our approach is very much the same as that PBE+U approach in the work of Da Silva and coworkers [88] except we used U = 6.0 eV for the 4f states of Nd, Gd, Dy, Er, and Yb, instead of the U = 4.5 eV for the Ce 4f used in Da Silva et al. [88]. The band gap for undoped lithium tetraborate has been estimated [89], by the above DFT approach, to be 6.48 eV, much less than the experimental value of 9.8 eV found in combined photoemission and inverse photoemission [48, 49, 89]. This is not surprising as the band gaps found in density functional theory of Li2B4O7 are generally observed to the underestimate of values obtained from combined photoemission and inverse photoemission experiments [48, 49, 89].

We built a cubic cell of Li16B32O56, as shown in Figure 9. Based on our EXAFS results that place the RE dopant in a Li+ site, one Li+ atom is then substituted by a Nd, Gd, Dy, Er, or Yb atom, representing 6.25% atomic doping which is much higher than the experimental level, but computationally tractable. Monkhorst-Pack [90] 2 × 2 × 2, k-points grids were adopted for Brillouin zone sampling. Geometry optimizations were performed for the coordinates of the atoms and the lattice parameters until the maximum force on the atoms was less than 0.01 eV/Å, confirming slight strain in the lattice in the vicinity of the rare earth dopant and dependent on the choice of the rare earth dopant. There is strong evidence of rare earth state hybridizations with the lithium tetraborate host, while the boron and oxygen are connected by valence bonds, but Li and borate are connected through ionic bonding, as is common in density functional calculations of lithium tetraborate [49–51] and is evident in the overlap of the partial density of states as plotted in Figure 10. This indicates that the Li+ site is also the most reasonable choice for substitutional rare earth dopants, because the borate B4O7 are mostly tied by strong covalent bonds, so a rare earth dopant is very unlikely to replace either B or O. The Li+, on the other hand, is bonded to the borate primary through ionic bonds, which is evident from the partial densities of states of Li2B4O7. Thus we feel that it is legitimate to substitute some of the Li+ by the rare earth atoms.
In previous work [89], we noted that the Mulliken bond population, which is a measure of overlap charges in the chemical bonds [91, 92] of B-O bond is about 0.58 to 0.82, whereas Li-O bond is less than <0.06. From this one can deduce that the B-O bond is in nature strongly covalent, and Li-O is most likely ionic. The bond lengths of the B-O and Li-O are 1.36–1.51 Å and 1.97–2.46 Å, respectively, the latter being a much better fit to the EXAFS data discussed above, for substitutional rare earth doping.

In Li2B4O7:Nd (Figure 10A) and Li2B4O7:Dy (Figure 10B), we observe that nearly all the unoccupied 4f levels hybridize with the lithium tetraborate conduction bands. This could explain the similarity of the edge shift uncovered by the Latin hypercube sampling (LHS) analysis summarized in Table 1 between Nd and Dy doped samples. We find that in Er the 4f levels, particularly the spin down component situated at EF do not mix with the host tetraborate, whereas at 2–4 eV above EF, the 4s state population is very low (Figure 10C). For Li2B4O7:Yb (Figure 10D), there are few unoccupied 4f states, which leads to a little depletions of the Yb 4f14 occupancy, unlike GaN:Yb [74]. For Nd (Figure 10A), Dy (Figure 10B), Er (Figure 10C), and Yb (Figure 10D) there is a significant 4f partial density of states that shows up within the lithium tetraborate band gap, but this is not observed for Li2B4O7:Gd. We find that the occupied Gd 4f states are embedded deep at the bottom of the valence band of the Li2B4O7:Gd valence band. The differences in the Gd electronic 4f state are also reflected in Table 1 from the experimental edge shift E0 being very different from the other doped samples. Overall we interpret the rare earth 4f state placement and the clear rare earth 4f hybridization to the lithium tetraborate lattice as contributing to the f to f transition spectral broadening, similar to our expectations for Er doped GaN due to the strong hybridization of the GaN matrix with the imbedded Er 4f states [74]. Such 4f states, as calculated here, do give rise to states within the band gap, not only as plotted in Figure 10, but are seen as sharp absorption lines in the transmission spectra at wave lengths greater than 375 nm, as well as reflected in the luminescence spectra of rare earth doped lithium tetraborates [27, 72, 73].

The correlation U has been applied, as noted, to the rare earth 4f orbitals only, the remaining various orbital subset of orbitals may in some cases have applicable correlation energies as well. There is no a priori exclusion of multiple correlation energies, nor of wave vector dependence of the various possible correlation energies and such complications might well exist. This could lead to an incomplete (or insufficient) description of orbital hybridization effects including the luminescent and optical properties. In general, the increased hybridization will decrease excited state lifetimes and increase luminescent spectral feature widths, including the f to f transition spectral features. The contributions to f to f transition spectral broadening, nonetheless, arising from the strong rare earth hybridization with the lithium tetraborate lattice, are significant even without considering the variations in oxygen coordination, although Li2B4O7:Yb (Figure 10D) may be the exception. The variations in oxygen coordination evident from the EXAFS, and expected for a glassy lithium tetraborate, will be even more significant because of the strong rare earth hybridization with the lithium tetraborate lattice, affecting the f to f transition spectral broadening to a great degree.

**CONCLUSION**

Previous studies of rare earth doped lithium tetraborate glasses revealed asymmetry in the RE 4f spectral emission lines. In order to determine the source of the spectral line distortion, X-ray absorption fine structure studies were conducted in order to extract the local environment surrounding the rare earth dopants. The near edge absorption spectra data analysis indicates that for all of the rare earth doped samples studied (Li2B4O7:Nd, Li2B4O7:Gd, Li2B4O7:Dy, and Li2B4O7:Er), the dopant substitutes into the Li+ ion sites as RE3+. The empirically determined site was then used to perform a density functional theory calculation and determine the electronic source of the asymmetry in the spectral emission lines.

As a result of the doping, there is a slight expansion of the coordination shells (O and B atoms) that surrounded the original Li+ atom from approximately 2.0 Å to approximately 2.5 Å, the exact value depending upon the size of the rare earth. The results for rare earth doped borates compare well with expected bonding distances when compared with rare earth coordination number and atomic radii from Shannon [93], the radial distributions functions obtained from X-ray diffraction [55] and consistent with prior EXAFS studies [66, 67]. The first coordination shell’s distance and coordination number (in the range of 6–8) (amplitude reduction factor fixed at 0.85) compares well with the expectations for a rare earth oxygen coordination environment and occupation of the Li+ site. Since these are an
average coordination number and coordination distance in the glass samples, it is expected that there are hypo- and hyper-environments throughout the glass that average out.

A qualitative XANES analysis confirms a $+3$ valence state and is consistent with our theoretical expectations. The resulting density functional theory calculations indicate there is strong hybridization with the unoccupied $4f$ orbitals with the host lithium tetraborate matrix. This hybridization is a likely source of the spectral emission line distortion observed when the glass oxygen positional disorder is also taken into account.
