Abstract

Internet Protocol Geolocation (IP Geolocation), the process of determining the approximate geographic location of an IP addressable node, has proven useful in a wide variety of commercial applications. Commercial applications of IP Geolocation include market research, redirection for performance enhancement, restricting content, and combating fraud. The potential for military applications include securing remote access via geographic authentication, intelligence collection, and cyber attack attribution.

IP Geolocation methods can be divided into three basic categories based upon what information is used to determine the geographic location of the given IP address: 1) Information contained in databases, 2) information that is leaked during connections with the IP of interest, and 3) network-based routing and timing information. This thesis focuses upon an analysis in the third category: delay-based methods. Specifically, a comparative analysis of the three existing delay-based IP Geolocation methods: Upper-bound Multilateration (UBM), Constraint Based Geolocation (CBG), and Time to Location Heuristic (TTLH) is conducted. Based upon analysis of the results, a new hybrid methodology is proposed that combines the three existing methods to improve the accuracy when conducting IP Geolocation. Simulations results showed that the new hybrid methodology TTLH method improved the success rate from 80.15% to 91.66% when compared to the shotgun TTLH method.

1. Introduction

The evolution of the Internet has revolutionized modern society by providing unprecedented access to information and knowledge to anyone, from anywhere, and at anytime. The systems, infrastructure, and networks that make up the Internet (collectively known as “Cyberspace”) transcend all physical boundaries. The Internet provides a means for anyone who has access to an Internet connection to collect or disseminate information on a global scale at a very low cost.

The increasing use and dependence upon cyberspace by public, private, governmental, and military organizations drastically increases our exposure to adversarial activities. Sophisticated hacking tools are freely available on the Internet and enable script-kiddies with few resources and little knowledge to conduct sophisticated information system attacks against individuals and organizations that rival those launched by well-resourced nation states. The purposes of these attacks can range from simple mischief to wide spread attacks against our critical national infrastructure. Our adversaries conduct intelligence collection activities on network connected DOD resources on a daily basis in order to collect, correlate, and exploit information for their nefarious purposes. In all of these cases, it is desirable to identify the ultimate source of
the attack (attribution). Identification of the source requires identification of the physical location of the attacking system (e.g., tracing the attack back and attributing it to a specific IP address), identification of the system(s) which are controlling the attacking system as in many cases the attacking system is an “agent” of the actual attacker, identification of the individuals responsible for initiating the attack, and identification of the organization that is sponsoring the attack. This thesis focuses on methods that address the first element: identifying the physical location of the system.

IP Geolocation is the process of identifying the approximate physical location of a networked device that is connected to the Internet based upon its IP address and communication characteristics. Various techniques for IP Geolocation have appeared in the academic literature [15] [6] [7], some of which have resulted in issuance of US patents, including one by the National Security Agency [16] [8] [1]. IP Geolocation methods can be divided into three basic categories based upon what information is used to determine the geographic location of the given IP address: 1) information contained in databases, 2) information that is leaked during connections with the IP of interest, and 3) network-based routing and timing information. The scope of this thesis is limited to analysis in the third category: delay-based methods for IP Geolocation. The narrow scope of the thesis was intentional and will fill a significant gap in the academic literature. The scoping of the thesis does not suggest that one should only use delay-based IP Geolocation methods. To the contrary, it is recommended that methods from multiple categories should be used to provide as much intelligence as possible. The data can be gained from multiple, non-overlapping, information sources.
IP Geolocation has proven useful in a wide variety of applications. To date, the use of IP Geolocation in published academic literature and applications have been primarily in the commercial arena. For example, commercial organizations are using IP Geolocation for targeted marketing [20]. This provides the ability for web site owners to identify the geographic location of a system accessing their web pages and customize their advertisements by promoting business that are in close proximity to the user. IP Geolocation has been used to combat identity theft. Irregular location patterns from single users would be able to trigger fraud alerts [20]. If a business can identify where a purchase request is coming from, they can act accordingly if the request is from a high fraud area. The result is that organizations can avoid losses and keep costs down. In some cases, knowing the location of the source of a network communication can prevent illegal activities. For example, despite the fact that online gaming web sites are accessible from anywhere on the Internet, gambling is not legal worldwide. Ensuring that users are located in areas where online gaming is legal can keep a business operating lawfully [10]. Law enforcement can use IP Geolocation to locate computer equipment suspected of being used for illegal activities.

While the military use of IP Geolocation is relatively new, it can provide enormous benefits. For example, IP Geolocation provides the ability to help secure remote access via geographic authentication, improve intelligence collection, and enable cyber attack attribution. The military significance of IP Geolocation has dramatically increased with the articulation of Cyberspace as a medium for warfighting within the United States Air Force (USAF) mission statement. On 7 December 2005, Secretary of the Air Force Michael Wynne adopted the new mission statement which states, “The
mission of the United States Air Force (USAF) is to deliver sovereign options for the
defense of the United States of America and its global interests -- to fly and fight in Air,
Space, and Cyberspace” [30]. Shortly after adopting the new mission statement, the
USAF announced plans for the creation of a new “Cyber Command” [31]. The Cyber
Command will be comprised of personnel specializing in the intelligence,
communications, operational, and engineering fields, with the stated goal to exploit
cyberspace and to defend our national cyberspace.

1.1 Problem Statement

Delay-based IP Geolocation methods provide the ability to geolocate an IP
addressable node based on network timing and routing information. Unfortunately, there
has been no comparative analysis of the accuracy of existing delay-based IP Geolocation
methodologies. For example, it is of interest to know how the positioning of nodes
within the network would impact the accuracy of various IP Geolocation methods.
Information gained from an analysis may enable an improvement of existing methods or
lead to the development of a new or hybrid methodology.

1.2 Research Objectives

The purpose of the research is twofold. First, it is desired to gain a complete
understanding of the accuracy of existing delay-based IP Geolocation methods. A
simulation-based study of the delay-based IP Geolocation methods will allow validation
of the existing IP Geolocation methods and provide a better understanding of the
sensitivity the methods have to the network infrastructure. Second, it is expected that the
knowledge gained from the analysis will enable the development of a new hybrid methodology for delay-based IP Geolocation that may improve the accuracy when compared to existing individual methods.

1.3 Research Methodology

This research will make use of the OPNET network simulation tool which allows the user to rapidly create and simulate network architectures [14]. OPNET has been successfully used in numerous network studies and is considered one of the best tools for accurate simulations of real-world network architectures [21][14]. In this research, various network architectures will be modeled and simulated in OPNET to provide insight into accuracy of delay-based IP Geolocation methods.

The process for conducting the research will consist of four steps. First, a Wide Area Network architecture consisting of 12 nodes and 14 routers across the USA will be modeled in OPNET to enable the simulation of network traffic. Second, multiple simulations will be conducted to collect the propagation delay from each node to every other node. Third, an analysis of the collected data using the Upper-bound Multilateration (UBM), Constraint Based Geolocation (CBG), and Time to Location Heuristic (TTLH) methodologies will be conducted. The results will be analyzed to identify trends in the data and to investigate the effect of positioning nodes. Finally, a new methodology of combining multiple IP Geolocation techniques will be developed to obtain more accurate results than using one methodology alone.
1.4 Research Significance

Determining the geographic location of a network node has proven to be important in a wide variety of commercial applications. The full potential of the military application of this technology has not yet been realized, but is expected to grow with the new emphasis on cyberspace. For this reason, we need to understand the strengths and weaknesses of the delay-based IP Geolocation methods. Developing an enhanced understanding of the technology will help us protect the knowledge of the location of our network addressable assets and assist the military community in locating the positions of nodes of concern.

1.5 Thesis Overview

Chapter one has described the background of IP Geolocation and enumerated some of its potential uses. It introduced the importance of IP Geolocation and focused on some of the purposes and uses in commercial and military applications. This chapter also briefly introduced the problem statement, research objectives, research methodology, and explained the significance of the research. Chapter two contains a more in-depth review of literature related to the topic of IP Geolocation. It also explains the terminology, the underlying calculations required for the delay-based IP Geolocation methods, the metrics for comparing the IP Geolocation methods, and how the metrics are can be compared to evaluate the accuracy of the various methods. Chapter three provides an overview of the research design methodology used in this study. It explains the rationale behind the research design and its appropriateness to answer the research objectives. Chapter four presents an analysis of the data collected from the research, identifies trends discovered
in the data, proposes a new hybrid IP Geolocation methodology, and provides a comparative analysis of the three delay based geolocation methods. Chapter four also presents results from a proposed hybrid geolocation methodology. Finally, chapter five provides a discussion on the research results and presents implications for future research.
2. Literature Review

2.1 Chapter Overview

The purpose of this chapter is to expand upon the information presented in Chapter 1 through a detailed review of the relevant literature. First, a high level review of IP Geolocation will be addressed to provide a basic understanding of the various methods that have been used to determine the geographic location of an IP addressable node when using all available information. Next, a detailed discussion of the delay-based methods for IP Geolocation will be presented to provide an in-depth understanding of the operation, strengths, weaknesses, and limitations of each of the methods. Finally, a discussion of recent thesis research in the area of delay-based IP Geolocation will be presented to motivate the scope of this thesis.

2.2 Definition of Terms

In this section, terminology is introduced to provide the reader with the knowledge necessary to understand the research presented in this thesis. Initial descriptions of the terms will be basic and may be later refined as necessary to further clarify their application in the research.

A “PING” command is used on a IP addressable node to determine the delay for information to travel through the network from one point to another [19]. PING commands are often used to insure that another system on the network is reachable and is currently “up” or able to answer requests for service [11].
The terms “end node”, “target node” and “polling node” are used to refer to the role that an IP addressable node plays in the research. An end node is defined as a network device that will respond to a PING request and which the geographic location of the device is known. End nodes are primarily used when discussing the TTLH IP Geolocation method because it determines which end node is located closest to a IP addressable node with unknown location. For the purposes of this research, any IP addressable node that responds to a PING request can be an end node.

A target node is defined as any IP addressable node network device that will respond to a PING request and which the geographic location of the device is unknown. The whole purpose of IP Geolocation is to identify the geographic location of an IP addressable node to some level of granularity. Target nodes are used in the research to identify the node that the IP Geolocation is attempting to locate. For the purpose of this research, the location of target nodes will be known and used to calculate the accuracy of the various delay-based IP Geolocation methods, but in a real life application of the methods the location of the target node would be unknown.

A polling node is defined as any IP addressable node network device that can generate PING requests and receive the resulting response. The polling nodes are controlled by the researcher and are used to send PING requests to both end nodes and a target node of interest. Polling nodes are the primary data collection mechanisms in all delay-based IP Geolocation since these methods require delay measurements to determine the approximate location of the target node.
In this research project, all nodes will be used as polling nodes, end nodes, and target nodes. This allows for a research design in which all of the data can be collected and later analyzed by the researcher to create multiple scenarios for analysis.

2.3 Internet Protocol Geolocation

Internet Protocol Geolocation (IP Geolocation) is the process of identifying the approximate physical location of an IP addressable, networked device that is connected to an IP based network based upon its IP address and communication characteristics. In most cases, the IP based network contemplated for use is the Internet as this is the application environment of current interest. However, it can be used in any IP based network such as the Secure Internet Protocol Router (SIPR) or the Joint Warfare Internet Communications Secure (JWICS) networks.

IP Geolocation methods can be divided into three basic categories based upon the information that is used to determine the geographic location of the given target IP address. Database focused methods rely upon information contained in databases; information leakage focused methods rely upon information that is leaked interactions with the IP node of interest, and network communication attribute-focused methods rely upon network, routing, and timing information which can be collected and analyzed to identify the location of the target IP of interest to some level of granularity [12].

2.4 Database Focused Methods

IP Geolocation methods in the first category are based upon information that is stored in public database (e.g., a WHOIS database or a Domain Name Server database).
These methods use the target IP address in conjunction with information that is stored within a database containing information related to the network structure, architecture, or topology.

2.4.1 WHOIS

WHOIS databases contain information that maps logical identifiers (domain names, IP addresses, AS numbers contained in routing tables, etc.) to real-world entities (company names, ISPs, telecommunication providers, etc.), which could reveal the approximate geographic location of the target IP address. The WHOIS command queries a remote database that contains information recorded when a network domain or IP address range was registered. It is possible to cache WHOIS lookups in a local database to accelerate, optimize, or correlate searches. NetGeo is a for-profit application that relies primarily on WHOIS for its basis of information. Using information from 2,380 IP addresses, NetGeo was found to have a median error distance of 650 km [15]. While this is a very large area, it meets the needs for the majority of the commercial applications that NetGeo supports. A critical weakness of WHOIS-based methods is that the accuracy of this method is dependent upon the accuracy of the information stored in the database. The data contained within the WHOIS database could be erroneous because it was submitted incorrectly, changes have occurred since the information was entered, or by intentional deception. As a result, the accuracy of this information may not be reliable and should not be solely relied upon. However, WHOIS lookups can be used to compliment other IP Geolocation methods when there is a requirement for increase accuracy and reliability.
2.4.2 Domain Name Service (DNS)

The Domain Name Service (DNS) is a standard distributed database used to manage the forward and reverse translation of Uniform Resource Locators (URLs) to IP addresses. For example, when the URL “http://www.cnn.com” is entered into a web browser, the web browser first sends a request to the local DNS server asking for the IP address that corresponds to “www.cnn.com”. Once the local DNS server returns the IP address that corresponds to the URL, the computer can now communicate over the network using IP protocol to retrieve the desired web page [18]. When domains are created, information is provided by the registrant including the administrative contact and address, the technical contact and address, and the IP address of DNS servers that will be responsible for conducting DNS translations for the new domain. The addresses provided by the registrant can be a useful clue when conducting IP Geolocation. In some cases, the target node may be located in close proximity to the local DNS server. By identifying the DNS servers that are used by the target node, one can infer its location. Unfortunately, the geographic region served by the DNS server could be quite larger resulting in a coarse granularity in the identification of the area in which the target node is contained. Once again, this information should be used with information gained from using other methods.

2.4.3 IP Clustering

IP Clustering makes use of the principal of locality to conclude that IP addresses that are located in close proximity to each other may be physically located near to one another. If we know the geographic location of an IP addressable node (or groups of nodes) that is close to the IP address of a target node, we can infer the target node
location. In some cases, organizations build databases from previous queries to the WHOIS database and augment it from knowledge gained from other sources. This method relies on keeping a large database and that can be cumbersome because IP addresses are not always static. The internet is designed and organized in a way that allows for IP addressable nodes to dynamically change which makes it extremely difficult to insure that information previously collected is still valid [15]. In addition, this method will not be accurate in instances of organizations that interconnect their geographically dispersed locations using dedicated Wide Area Network (WAN) or Virtual Private Network (VPN) communication links. In these cases, a WHOIS query or other information may identify the target IP address as physically located at the organizations main headquarters while in reality it is located at a satellite office located very far away from headquarters. This occurs because the organization assigns IP addresses for their remote offices from the same block as those in the headquarters. This is a common situation in organizations with high level security requirements that mandate that the internal organizations be connected to the Internet via a single point. This security architecture is used to enable security monitoring, policy compliance, and auditing of all organizational traffic.

2.5 Information Leakage-Focused Methods

IP Geolocation methods in the second category are based upon information that is leaked from the IP address of interest during network communication interactions between network nodes. The information gained can be through legitimate mechanisms
designed into the communication infrastructure or can be inadvertently and unknowingly leaked from a target.

2.5.1 Reverse DNS

Reverse DNS lookups are used to convert an IP address into a system name and domain name. A DNS server database often has information about the geographic location of systems that they serve embedded into the system names. A reverse DNS lookup of an IP address can reveal the system name and/or domain name which may contain clues about its geographic location. These clues include the city, state, and region names; airport codes; or organizational names which can be used to identify location [12]. Administrators commonly use location in the naming of devices for ease of recognition of the location of the device. This is often done for efficiency so that when they encounter a problem with the node, they can find the troublesome device quickly [4]. DNS servers also optionally contain a record that identifies the latitude and longitude of the DNS server. The embedded information can provide valuable information aiding in IP Geolocation. However, this method is subject to deception and may not be reliable as discussed above due to the inherent dependence upon how the information is entered and maintained in the database.

2.5.2 Trace Route

A “TRACEROUTE” command is used to determine the current pathway by which information travels through the network from one point to another. The details of how TRACEROUTE works will be discussed in a later section. A TRACEROUTE command will identify all of the intermediate network routers that network communications pass through from the source (polling node) to the destination (target
node). Since the routers are often named based upon their physical location, their names can yield valuable clues about their geographic location. If one can locate the last router in the chain, one can infer that the target node is geographically near the last router.

Deception and social engineering can be used to entice a user to leak information. For example, consider a stealth counter intelligence web server which appears as a non-military, non-governmental resource that serves satellite imagery that is desirable to our adversaries. The user could be asked for their ZIP code or other unique geographic identifying information under the guise of enhancing the user’s experience. Once this information is collected, it can be archived in a database for future use. The database can then be accessed as a compliment to other information resources when conducting IP Geolocation [29].

2.5.3 Application Information Leakage

Application programs can also leak information without the user’s knowledge. For example, by design a web browser can provide information such as language, operating system, browser name, and time zone [18]. Organizations often leak clues about their location by their domain names. Some well-known examples are country code top-level domains such as .au (Australia), .de (Germany) or .uk (United Kingdom) [4]. While the granularity of these methods is coarse, it does provide useful and collaborating information. Other domains such as .mil, .edu, and .gov do not use a country code but they are all assigned within the United States. Interestingly, airport codes are often used in the naming conventions of network routers. By looking at the router names to which a user is connecting, clues to the location can be found [12].
2.5.3.1 Finding End-User IP Addresses

Java can be used to find the IP address of a computer that accesses a web page even when the user is connecting to the internet through a proxy [17]. A web page can use simple java applet programs that request a computer assessing the web page to make another connection to the web server [5]. That java enable connection requests information such as the IP address of the computer making the connection [12].

2.6 Network Communication Attribute-Focused Methods

IP Geolocation methods in the third category are based upon information collected using network, routing, and timing information. An analysis of IP Geolocation methods in this category are the sole focus of this thesis. Each of these methods make use of the delay for information to be sent and received between nodes. For this reason, the following discussion will discuss each of the factors which determine the delay through a network connection.

2.6.1 Delay Factors in IP Network Communications

Consider an ideal situation where network traffic passes from a sending node to a receiving node via a fixed path through the communication infrastructure elements (e.g., hubs, switches, routers, gateways, firewalls, communication links). Even in this simple case, the delay between two nodes is highly variable. The factors that contribute to the variation in delay include, but are not limited to, the network topology, switching speed, line speed, network loading, and queuing delays [3] [26]. Since all delay-based IP Geolocation methods use delay measurements as a means to determine geographic distance, it is important to understand these primary sources for delay.
2.6.1.2 Topology

Network topology is the physical infrastructure that the network traffic traverses and is typically thought of as the primary determinate of the overall delay. The network topology constrains the physical path by which the message can travel. The network topology can be categorized based upon the location of the given communication path element of interest in the chain from the source node to destination node [25].

Source and end node systems are usually connected to a Local Area Network (LAN) which is then connected to the Internet through the network infrastructure. LAN elements consist of hubs, switches, access points, and firewalls. Typically, a LAN is then connected to a Backbone Network (BN) within the organization that links together LANs. The BN is comprised of a collection of higher speed communication lines, servers, routers, and gateways [23]. In smaller organizations, the BN will connect to the Internet via an Internet Service Providers, (ISPs) Point of Presences (POP). The POP is the pathway by which organizational network traffic connects to the Internet. In larger organizations, the BN network may be connected to a larger network as discussed below.

A Metropolitan Area Network (MAN) is a network that covers the area of approximately the area of a city. MANs are used to interconnect BNs and to provide a connection to higher speed WANs. As a result, the equipment used in a MAN is often fiber based and transports network traffic at higher data rates [9]. MANs can be implemented using circuit switching, packet switching, frame relay, or asynchronous transfer mode communication links [23].

A Wide Area Network (WAN) is a network that spans a geographic area larger than that of a MAN. WANs are used to connect networks within a nation or
INTERNATIONAL. In most cases, computer network WAN traffic travels over the same point-to-point high speed communications links used for carrying digitized voice communications for telephone networks. WANs are typically implemented by using high speed point-to-point circuit switching, packet switching, frame relay, or asynchronous transfer mode communication links [23].

LANs, BNs, MANs, and WANs are interconnected to provide a physical path from the source node to the destination node. The network topology contributes to the delay because it defines the physical path through the network infrastructure that the message takes from source to destination. The complete path that the message travels is known as the “network distance”. The network distance is determined by how the networks are interconnected within the organizations containing the nodes as well as how the organizations are connected to the Internet POP. For example, individuals in the Dayton, Ohio metropolitan area who use a Time Warner cable modem to connect to the Internet are connected first to the Time Warner internal network. The Time Warner internal network uses a combination of LAN, MAN, and WAN networking technologies to interconnect Time Warner customers across the state of Ohio. Time Warner has two POPs in Ohio: Columbus and Cincinnati. If a Time Warner cable modem user in Dayton connects to a web site located outside of the Time Warner private network, the traffic must first travel to either Columbus or Cincinnati where it enters the Internet POP. The Internet POP then routes the message to the appropriate location based upon its IP address. The route that the message takes can be over any of the numerous Internet providers that are connected to the POP.
2.6.1.3 Line Speed

Line Speed is a generic term used to describe the rate that data can travel through a given network segment via the specified medium. The medium acts as a conduit through which the message will travel. Depending on the location in the network hierarchy, different line speeds will be present. In the LAN, there is typically 10BaseT (10 Mbps) or 100BaseT (100 Mbps) hardwired networks. BNs employ higher speed systems with hardwired or optical networks running at 1000 Mbps or higher. MANs often employ high-speed digital fiber optic networks running from 1 Gbps to 40 Gbps. WANs use a variety of technologies including high-speed digital fiber optic networks running at speeds greater than 10 Gbps, microwave links can run at data rates of 274 Mbps, and satellite links that vary from 12 Mbps to 135 Mbps [23].

2.6.1.4 Queuing Delay

Network infrastructure elements such as routers often must handle a large amount of traffic during normal operation. When the router receives a message before it has had a chance to send a previous one, it will stack the messages awaiting transmission in a queue [18]. The result of a message being temporarily stored in a queue is delay. Many factors impact queuing delay such as the network congestion, amount of demand, and the processing speed of the network device. Excessive queuing delay can cause delay-based IP Geolocation methods to arrive at incorrect results. In most cases, this can be accounted for by sending multiple messages between the source and destination node over a variety of time, day, and weeks and at varying times of day over many days and choosing the minimum delay that is experienced. This method relies upon previous research that showed that there is a high probability that some of those messages reaching
the destination will not experience excessive queuing delays along the path [3]. Previous work determined that using the minimum time yielded better results than using averages [3] [21]. Finding the minimum response time is accomplished by sending many requests over a short period. Some of those requests will make it to the destination without waiting for retransmission. This delay is taken as the best-case scenario processing time by the end nodes and all of the network infrastructure elements. While this is not insured, the fact remains that the delay between two nodes can never be less than the delay through a given network under ideal conditions. For this reason, the minimum delay times are used instead of the average delay times. By using knowledge about the network, the network delay sampling times can be strategically selected to occur when the network is idle or under minimum loading conditions.

2.6.1.5 Switching Speed

Network traffic must propagate through the network infrastructure devices that connect the source and destination node. Network infrastructure equipment such as repeaters, routers, switches, hubs, or bridges result in a delay that is different than the contribution from network topology, line speed, or queuing delay [18]. The delay is a function of the design of the infrastructure element and the domain translation(s) which must occur to implement the functionality of the device. For example, fiber optic transmission systems must convert electrical signals to optical signals when transmitting data and must convert optical signals to electrical signals when receiving data. Since the connection from source to destination will traverse multiple network infrastructure devices, each one contributes to the overall delay through the network. For example, in a router even if there is no other traffic to cause a queuing delay, there is a finite amount of
delay required to receive data, process it, and send it out to another network interface. While switching delay can be significant, the NSA found that a packet travels through a switch in two milliseconds 95% of the time [8].

### 2.6.1.6 IP Path Diversity

The design of the Internet Protocol is such that Internet traffic does not necessarily follow the shortest path from origin to its destination. Furthermore, traffic does not always take the same path from source to destination [25]. This is an intentional design choice made to increase the resilience of the network to infrastructure element failures or excessive delays in infrastructure elements. The distributed nature of network routing decisions and adaptive routing algorithms means that network traffic will be routed based upon dynamic network and operational factors. The result is that network traffic from the same network connection does not always follow the same path from one packet to another [18]. Consider a network infrastructure where traffic is delivered faster when it travels from source to destination through three routers connected via high-speed links versus traveling through two routers connected via a lower speed link. Thus, the best quality connection does not always mean that it will traverse the least number of hops to the destination. Now, consider when one of the high-speed links between the routers becomes overly saturated resulting in excessive delay. The router nearest the source may decide to route the traffic via the lower speed connection because it is currently faster than the saturated high-speed link. Due to the dynamic nature of routing, it is important to characterize the delay between end nodes a number of times, over a variety of times of days, days of the week, and weeks during a month.
2.6.2 Measuring Delay

Previously, the PING command was briefly introduced as a tool for making delay measurements. PING works by sending an Internet Control Message Protocol (ICMP) Echo Request packet from the source node making the request to the destination node [11]. The outbound request sent by the source node has a message field that includes a timestamp that is used, in part, to calculate a round trip time once the echo request is replied and received [26][11]. When the receiving node receives a Echo Request packet and if it is configured to respond, it will respond to the request by sending a ICMP Echo Reply packet back to the sender. When received by the originating system, it can calculate the difference in time from when the message was sent to when the reply was received. This calculated time is known as the Round Trip Time (RTT). The RTT can be divided by two to estimate the one-way delay time from source to the destination. In this research, the delay time between nodes is calculated using this method. The PING command has a margin of error of four milliseconds [26][19]. In most cases, this is sufficient to diagnose network connections or determine the amount of loading that the infrastructure is currently experiencing.

In some cases, tools other than PING tools can be used to collect delay measurements when a finer resolution is required or precise time measurements in each direction are required. For example, some satellites network configurations use the satellite for transmission in one direction while the data is transmitted over terrestrial lines in the other direction. Unless accurate measurements are collected in each direction, asymmetric communication channels can give misleading delay measurements when using PING. One way to measure delay more precisely is to use the computer’s
clock for measurement. In this case, the outgoing messages not only include a
timestamp, but also a stamp that counts the number of computer cycles the processor uses
between the sent and received transmission. Current generation computer processors
running at more than 1 GHz allow for measurements of time to be in the microsecond
level. This resolution is necessary when correlating delay measurements to distance
calculations, especially when every microsecond could equate to a message traveling
approximately 200 kilometers [7].

2.6.2.1 Trace Route

As previously discussed, the TRACEROUTE command is another tool that is
frequently used by network administrators. The TRACEROUTE command also makes
use of specially configured ICMP Echo Request packets. One of the header elements of
an IP datagram is the Time To Live (TTL) field. The TTL field is an 8 bit, unsigned
quantity that can range from 0 to 255. The TTL field was designed into the IP protocol to
insure that all network messages will be dropped after a specified amount of time.
Normally, the TTL field is initialized by the sending system to the maximum value (255),
and is decremented by one as it passes through each of the network routers. If a router
decrements the TTL field to 0 on an incoming network packet, it will drop the packet.
This will insure that traffic traveling through an endless loop will eventually be dropped
preventing network saturation due to erroneously designed or implemented networks.
When a router drops a packet, it will inform the sender that it had to do so via an ICMP
status message. This is what makes the TRACEROUTE command possible.
For example, when a TRACEROUTE command is issued, the sending system addresses the packet and sets the TTL to 1. The packet travels to the first router which decrements the TTL field to 0. Since the TTL is now zero, the router drops the packet and sends a status message to the sending system. The status message contains the IP address of the intermediate router. The sending system records the returned router message, and then sends a new packet to the destination with the TTL set to 2. The process above is repeated and the second router status message is recorded. The process is repeated until a trace from the source to the destination is completed.

The TRACEROUTE command shows the IP address of each device between the original and the destination node. A common use of TRACEROUTE is for an administrator to find which device is not responding in the network. A graphical version of the TRACEROUTE, known as Visual Route, works the same way TRACEROUTE does [32]. Visual Route adds a graphical user interface and also uses NetGeo to help determine the location of the devices. NetGeo uses information entered by administrators to determine the locations of the routes taken [25].

2.7 Delay-Based IP Geolocation Methods

In this section, existing methods for delay-based IP Geolocation are reviewed. Delay-based IP Geolocation provides an attractive means for conducting geolocation because it does not rely upon the accuracy of information entered by others and delay measurements are not easily corrupted, neither purposely or inadvertently, as database methods can be. There is a significant gap in the academic literature when comparing the
accuracy of existing IP Geolocation methods. For this reason, this thesis focuses upon an examination of delay-based IP Geolocation methods.

2.7.1 Upper-Bound Multilateration

Initially, delay-based IP Geolocation methods were focused upon multiplying one-half the RTT by some scale factor to determine the distance between the polling node and the target node. By PINGing from a number of different geographically separated nodes, one can draw circles on a map around the polling nodes and see where the circles intersect which (ideally) indicates the geographic location of the target IP address. Upper-bound Multilateration [15] is a method that uses triangulation to find the location. While triangulation is the common term, multilateration is the more accurate name. Triangulation refers to an angle-based methodology when using three reference points [7]. Multilateration uses more than three reference points to further refine the estimation of the target location.

There is a common notion that the correlation between delay and actual distance is poor [2]. One reason for this is that network traffic does not travel in straight lines nor even in the most direct path to the host. However, some research has found success in countering this notion. To accomplish correlating distance to delay, first the one-way delay time must be determined. That time is then multiplied by 2/3 the speed of light to find an upper bound on distance that the target is away from the polling station. The rate of 2/3 the speed of light was the average speed that network traffic was found to travel through various media [17]. With the use of three polling stations, the researcher can look
at the distances and conclude that the target resides in the area where the distances overlap as shown in Figure 1 below.

![Figure 1. Delay Triangulation IP Geolocation Method](image)

One interesting side effect of this method is that it has an error checking algorithm built into it. When the upper bound is underestimated, the intersecting area will not include the target location. If the correct location of the target was in the area of each circle, the circles will always have an area of overlap. By plotting the areas, a mistake can be found if the circles do not overlap at some point. This may, in fact, be the best feature of the method because it is an error checker for the data collection [12].
Research has shown that correlating actual distance to delay is reasonably accurate when the distances are large in scale such as from an area the size of a continent. Research has shown that the method has been able to correctly find the location of a target to within 100s of miles [7]. The messages that were sent and measured traveled long distances and the distance traveled was a large factor in the delay. In geolocation methodologies that research nodes from a smaller area, messages travel shorter distances therefore factors such as queuing delay, and switching speed play a bigger factor in the equation. The distance traveled is still a factor in the delay, but not as prominent as it is when traveling hundreds or thousands of miles.

2.7.2 Constraint-Based Geolocation

Constraint-Based Geolocation is a method that was proposed that recognized that the rate of transmission is not always a constant 2/3 speed of light [7]. This improved upon the previous method using a calculated scale factor which depended upon the network infrastructure between the polling node and other known end nodes. Each polling node would poll a number of geographically dispersed nodes at known distances and then calculate a scale factor based upon the delays. The delay to the target node would then be multiplied by the scale factor and the circle drawn around the polling node. This process is repeated for each of the polling nodes within the polling node set.

To accomplish IP Geolocation by this method, the location of a variety of end nodes must be known. Once that is determined, the location can be found by comparing the delay times of the target node with that of the known end nodes. The end node with the delay time nearest to the target will be the end node that is closest to the target.
Methods such as GeoTrack use this method [15] while other research projects use variations of this method [8][32]. While this method does not allow you to pinpoint exactly where the target is, it can give an approximate location which is good enough for the intended application.

Some other conclusions can be made by correlating delay to distance. The speed of light can be used as the absolute upper bound for determining distance. Traveling at the speed of light, it would take a message 134ms to circumvent the equator. Internet traffic travels slower than the speed of light so if the round trip time of a message is less than 67ms one can conclude that the target is located on the same side of the globe. Network traffic can also travel through satellites positioned in geosynchronous orbit. Those satellites are located 22,000 miles from earth in outer space. A message traveling at the speed of light would take 478ms to travel to a satellite and back to earth. Messages that have round trip times shorter than 478ms did not use a satellite to reach the destination [21].

Previous research has had success correlating an actual distance to delay on a large scale. The accuracy of the previous CBG research was able to find the location of the target to within 120 kilometers [7]. An accuracy rate of 120km is a good result when looking at areas starting at the size of a country.

2.7.3 Nearest Known Node

The National Security Agency (NSA) holds a patent on a methodology for locating devices by using delay measurements known as the Time To Location Heuristic (TTLH) method [8]. The methodology attempts to find the nearest end node with a
known location to the target node. The result is not a precise location but rather the location of the previously known node that is closest to the target. The nearest end node is determined by polling the delay from multiple locations and comparing the delay measurements from the known nodes with that of the target node. The comparison is done using the Euclidean distance formula. The primary motivation for development of this method was to account for delays introduced by line speed, switching speed and queuing delays. By identifying the nearest node, many of the variations in delay are normalized because nodes in close proximity to the target will experience similar delay phenomena.

TTLH works best over long distances when the delay is dominated by line speed delay. When switching delay is dominate, such as within a campus or across a city, TTLH is not as accurate because the delay spent in switches becomes a larger factor in the delay than the network topology. TTLH uses multiple polling nodes and requires multiple end nodes with known location that are in proximity to the target node. In fact, the granularity of the method is determined by the distance between the end nodes and the target IP address.

The TTLH method builds upon research that found a correlation between delay time and location [8]. The time to location approach finds the proximity of a location by using a set of polling nodes and end nodes, then comparing delay times to determining which end node is in closest proximity to the target. To establish what the delay is, PING messages are sent from the polling nodes to the end nodes and to the target node. The RTT is then charted.
In order to account for delay from line speed and switching speed a hypothetical 0-bit packet is sent [3] [26]. This is accomplished by sending multiple messages at sizes of 64, 128, 512, and 1024 bits. Next the latency is charted on a graph and the y intercept is used for a hypothetical 0 bit packet, as shown in Figure 2 [3] below.

![Figure 2. Hypothetical Zero-Bit packet](image)

The minimum time is used for each packet size to determine the best fit. The resulting theoretical “zero-byte” packet would take zero time to switch and zero time to transmit through a medium thus resulting in a measurement that takes out the delay factors of line speed and switching speed [26].

The quickest time is used in the ‘zero-byte’ calculation to account for queuing delay. The packets are sent multiple times over a short period of time and collected
during different times of the day and over many days. Theoretically, some of these messages will get through without being held in a queue. The messages that do not experience a queuing delay will be used for the calculations. Previous research has found that the messages sent at times when network loads are small have the smallest queuing delay and result in the best data [26]. A traffic analysis of the network of interest is required to select the ideal time to collect measurements. If this is not available, a uniform sampling across a 24 hour period can be conducted and the minimum time selected. Messages sent at other times of the day should have more network traffic to compete with, but if the background traffic is consistent, the TTLH method will still produce the correct result.

2.7.3.1 Euclidean Distance

The Euclidean distance formula shown in Equation 1, is used to find the nearest known node to the target. The equation uses a limit but instead of finding the greatest distance as the limit approaches one, it can be used to find the nearest location as the result is closer to zero.

\[
d_e = \sqrt{\sum_{i=1}^{p} (x_{ie} - x_{it})^2}
\]  

The Euclidian Distance formula is used to find the nearest known end to the target node. The Euclidean distance is the square root of the sum of the squares of the delay between the end node and target node. In this formula, \( e \) represents an end node. This
The equation is solved for each end node. The end node, or \( e \), with the lowest value is the closest end node in the dataset to the target. The equation is solved by using the delay from all of the polling nodes to one end node and comparing that with the time from the polling nodes to the target. \( X_{ie} \) is the time for the message to travel from the polling node to the end node, \( X_{it} \) is the time from the polling node to the target node, \( p \) is the number of polling nodes used in the TTLH example. This is repeated for every end node. Then it concludes that the end node with the smallest Euclidean distance is the end node that is closest to the target. The results of this equation result in a number, but that number cannot be directly converted to a distance. An example of this is shown below in Figure 3.

Figure 3. Euclidean Distance Methodology
Polling Node 1 sends requests to end node 1, end node 2, and the target. These delay times are represented by $a_1$, $a_2$, and $a_t$. Polling Node 2 also sends a request to end node 1, end node 2 and the target. Those delay times are represented by $b_1$, $b_2$, and $b_t$. Next, by using this simple data set, Euclidean distances could be found as shown below in Equation 2:

\[
d_1 = \sqrt{(a_1 - a_t)^2 + (b_1 - b_t)^2}
\]

\[
d_2 = \sqrt{(a_2 - a_t)^2 + (b_2 - b_t)^2}
\]

(2)

Then once the equation was solved if $d_2$ was less than $d_1$, we could conclude that $d_2$ (end node 2) is closer in location to the target than $d_1$.

Simulation and experimentation have been used to measure the effectiveness of the TTLH method over a variety of network architectures and scales. Clarson [3] showed that TTLH worked within a building by correctly identifying to which switch in the building the target node was connected. He first simulated the local area network in OPNET. Then he conducted a controlled experiment was carried out on a LAN. The results of the experiment showed the location of the target was accurate only when an end node was located on the same switch as the target. This result was the first indication that TTLH was not reliable when the network distance was small.

Sorgaard [18] conducted simulations in OPNET to show how multiple autonomous system (AS) networks would affect the results when using the TTLH method. His simulations showed that the method was accurate in a single AS, but was
only successful 71.4% of the time in a multiple-AS network. In his work, models of the underlying infrastructure of the MCI and AT&T networks were constructed within OPNET to allow the simulation of the network environment. It was hypothesized that TTLH would have to be modified to account for link speed between AS in order for the results to be successful more often. Unfortunately, no mechanisms were proposed to account for link speed variances.

Turnbaugh conducted an experiment where he used publicly available “looking glass” servers that are located throughout the United States [26]. He was able to control them to poll target nodes and end nodes located throughout the country. The results correctly identified which end node city was closest to the target 100% of the time for five out of the six targets. The sixth target was a case that had multiple end nodes located within 100 miles of the target node. However, the TTLH method did not return accurate information when multiple end nodes were located near the target node. It correctly identified the nearest known node when the target node only had one end node located within 100 miles of it. When conducting the experiment, polling sets of seven, eight, or nine nodes were used because previous researchers theorized that these numbers of polling nodes would allow for the most accurate measurements [15].

2.8 Summary

This chapter provided a review of the relevant IP Geolocation literature. It first examined existing methods for determining the geographic location of IP addressable nodes. While IP Geolocation is accomplished through a variety of methods, delay-based methods use real-time delay measurements and are the least dependent upon external
information sources. A review of the terminology used in the thesis was presented to provide the reader a basis for interpreting the research design. In addition, a review of computer networking architectures and factors that contribute to network delay was required so that the reader would understand the research.

While the literature review revealed three methods for delay-based IP Geolocation, there is no existing research which compares the accuracy of each of the methods. For this reason, this thesis will focus on a comparative analysis of delay-based IP Geolocation methods.
3. Methodology

In this chapter, the complete research design is reviewed to provide the reader a detailed understanding of how the research data will be collected and analyzed. First, a brief overview of the OPNET network simulation package that will be used in the modeling and simulation of the networks is presented. Second, the network architecture that will be modeled in OPNET and used for data collection is introduced. Third, an overview of the data collection process is reviewed to provide the reader the ability to duplicate the results. Fourth, the calculations required for Upper-bound Multilateration (UBM), Constraint-Based Geolocation (CBG), and Time to Location Heuristic (TTLH) IP Geolocation methods investigated in this project are explained in detail. Finally, the metrics by which the accuracy of the methods will be compared is presented along with all assumption made in the analysis.

3.1 Simulation Tools

The OPNET network simulation package provides the ability to rapidly model and simulate network architectures [14]. OPNET has been successfully used in a variety of network studies and is considered one of the best tools for accurate simulations for real-world network architectures [21][14]. One key benefit of OPNET is that it offers a number of predefined templates that model a variety of different network architectures. All models in OPNET can easily be parameterized to provide the simulation of realistic, non-ideal networks across a variety of operational situations [14].
Each of the network architectures used in the research will be modeled and simulated using OPNET version 12.0 running on a Dell Precision Workstation 690N - 1KW. dual core Intel Xeon® Processor running at 3.0GHz with a 4MB L2 cache and 4 GB of system RAM.

3.2 Network Architecture

A Wide Area Network (WAN) architecture model based upon an OPNET template will be used as a basis for the simulation and data collection in this research. A WAN network was chosen because the literature review revealed that the delay-based methods for IP Geolocation worked well when the geographic distance between nodes was large. The network model consists of fourteen routers graphically dispersed across the United States of America which interconnect twelve polling nodes located in different cities throughout the United States as shown in Figure 4. The nodes contained in the model were located in Boston, Hartford, Houston, Jacksonville, Los Angeles, Miami, New Orleans, New York, San Diego, San Jose, Seattle, and Tampa. While the network architecture was fixed, each of the twelve nodes could be considered as an end node (E), polling node (P) or the target node (T) depending on the specific simulated model under consideration. A listing of the twelve cities and their node designators are shown in Table 1.
The initial research focus is upon the impact that network topology has when conducting delay-based IP Geolocation. As a result, the modeled network architecture is selected so that there are a variety of distances between nodes to enable the investigation of various network architectures without requiring the explicit reconfiguration of the model. Each network link simulates using an OC-3 link. The network is configured to be unloaded (e.g., no background traffic) to prevent queuing delays. Switching speed is assumed constant in this research because of the limited number of network nodes. Further, the literature review revealed that almost all messages travel through a switch in less than two milliseconds [8].

Once an analysis of impact network topology has upon the accuracy of the delay-based IP Geolocation methods, if time permits analysis of other factors will be conducted.

#### 3.3 Enumerating Network Architectures

While the network architecture is constrained by only containing twelve nodes, there is a large number of possible subsets of the overall network architecture that will be used in the analysis phase of the research. The process by which each unique network configuration is as shown in the pseudo code shown below in Figure 5:

```plaintext
for(Target=1; Target <=12; Target++)
{
    for(NumPolling=2; NumPolling<=9; NumPolling++)
    {
        Enumerate All Combinations of NumPolling nodes
        {
            Enumerate All Combinations of (11-NumPolling) End nodes
            {
                /* analyze data */
            }
        }
    }
}
```

Figure 5. Network Architecture Enumeration
Once a network architecture is enumerated, the delay data will be analyzed using each of the three delay-based IP Geolocation methodologies.

3.4 Data Collection Process

Since each of the nodes can serve as a polling node, an end node, and a target node during any given simulation, delay measurements for all possible combinations of the twelve nodes will be collected at one time. Data will be collected by configuring the OPNET simulation so that every node PINGS each of the eleven remaining nodes. Since data will be collected for each node, a 12 by 12 matrix will be constructed which contains 132 points of data as shown below in Equation 3:

\[
\begin{bmatrix}
0 & D_{1,2} & D_{1,3} & \ldots & D_{1,11} & D_{1,12} \\
D_{2,1} & 0 & & & & \\
D_{3,1} & 0 & & & & \\
& \ddots & \ddots & \ddots & \ddots & \ddots \\
& & & & & \\
D_{11,1} & 0 & & & & \\
D_{12,1} & & & & & \\
\end{bmatrix}
\]

\[
\text{Delay} = \begin{bmatrix}
0 & D_{1,2} & D_{1,3} & \ldots & D_{1,11} & D_{1,12} \\
D_{2,1} & 0 & & & & \\
D_{3,1} & 0 & & & & \\
& \ddots & \ddots & \ddots & \ddots & \ddots \\
& & & & & \\
D_{11,1} & 0 & & & & \\
D_{12,1} & & & & & \\
\end{bmatrix}
\]

Note that the delays on the diagonal are zero due to the delay between any node and itself is zero. For completeness, the delay between any two nodes is not assumed to be symmetric. This is an important reality that must be accounted for in the analysis.
phase to account for modern asymmetric network architectures. Asymmetry can come from differences in network architecture on the return path (e.g., satellite downlink with terrestrial return path) or differences in line speed. One limitation of using PING is that the delay measured is the Round Trip Time (RTT) which must be divided by two to estimate the one-way distance between the polling node and the target node. In an asymmetric network, this estimation may induce errors into the findings.

Once the delay data is collected, it can then be analyzed in multiple ways by theoretically changing the numbers and locations of each of the polling, end and target nodes. Specifically, the data will be analyzed for each possible unique network configuration as identified in the enumeration of network architectures section above.

### 3.5 Data Analysis Process

In this section, the process by which each of the delay-based IP Geolocation methods will be applied to the collected delay data is reviewed in detail. Specifically, the calculations required for Upper-Bound Multilateration (UBM), Constraint-Based Geolocation (CBG), and Time to Location Heuristic (TTLH) methods is reviewed. A computer program was written in the “C” programming language to make all of the calculations necessary for each of the delay-based IP Geolocation methods (see Appendix A).

#### 3.5.1 Upper-Bound Multilateration (UBM)

The UBM method requires that the delay between two nodes be multiplied by a constant, 2/3 the speed of light (~124,000 mi/sec), to estimate the distance between the
polling node and the target node. The round-trip time collected in the data collection phase will be divided by two to estimate the one-way delay between the polling node and the target node. The resulting product results in a pessimistic of the distance between the polling node and target node [17]. Equation 4 shows how the calculation to estimate the distance will be calculated:

\[
\text{EstimatedDistance}_{\text{UBM}} = \left( \frac{2}{3} c \right) \left( \frac{1}{2} RTT \right)
\]  

(4)

Once the estimated distance using the UBM method is calculated, the estimated distance to other nodes to the target node can be calculated and circles drawn around each of the polling nodes. The intersection of the circles provides the multilateration necessary to localize the geographic location of the target node. For example, if there is a delay of 0.03083 between two nodes A and B, using the UBM we would obtain the result shown in Equation 5 below

\[
\text{EstimatedDistance}_{\text{UBM}} = (124188.16)(0.015415) = 1914.36 \text{ miles}
\]  

(5)

3.5.2 Constraint-Based Geolocation (CBG)

The CBG method is similar to the UBM method in that it multiplies a rate times a delay. However, instead of using a fixed constant rate, it requires the calculation of the Best Line rate based upon analysis of the delay data involving all nodes other than the target node. The calculated rate Best Line Rate is then used to estimate the distance between the polling node and the target node. Once again, the round-trip time collected
in the data collection phase will be divided by two to estimate the one-way delay between the polling node and the target node. The resulting product results in a distance that is less pessimistic estimate of the distance between the polling node and target node when compared to the UBM method [7]. Equation 6 shows how the calculation to estimate the distance will be calculated:

\[
\text{EstimatedDistance}_{\text{CBG}} = \left( \text{BestLineRate} \right) \left( \frac{1}{2} \text{RTT} \right)
\] (6)

The Best Line must first be calculated for each polling node when considering each of the other nodes as a target and the remaining nodes as end nodes. For this reason, there are theoretically 132 unique best lines, and hence 132 unique Best Line rates. However, in reality many of the Best Line rates will be the same because the Best Line is determined either by two nodes or by a single end node and the origin. The Best Line is determined by finding a line that is close to, but below all data points and has a non-negative intercept. If a proposed Best Line would cross the y-intercept at a negative number, the origin point (0, 0) was used to avoid any negative distance measurements. The slope of the line will determine the Best Line rate used to estimate the distance based upon the delay. Once the line is drawn and the x intercept is determined, the Best Line rate can be calculated by using any point on the line as shown in Equation 7 below.

\[
\text{BestLineRate} = \left( \frac{y-b}{x} \right)
\] (7)
For example, consider how the Best Line rate is calculated for Boston (P1) as the polling node and Tampa as the target node (T12). In this case, the delay between the polling node (e.g., Boston) and all other end nodes (e.g., Hartford, Houston, Jacksonville, Los Angeles, Miami, New Orleans, New York, San Diego, San Jose, Seattle) is plotted with distance on the x-axis and delay on the y-axis as shown in Figure 6. The Best Line is the line which fits below all of the plotted points, but does not have a negative y-intercept. In this case, the y-intercept is positive (approximately 0.0075) and thus the given line is the Best Line.

![Graph showing Determination of the Best Line Rate for Polling Node Boston (P1) and Target Node Tampa (T12)](image)

Figure 6 - Determination of the Best Line Rate for Polling Node Boston (P1) and Target Node Tampa (T12)
In this example, the slope of the line is calculated as shown in Equation 8 below by using any point on the Best Line (e.g., 500 miles, 0.015 seconds):

$$\text{BestLineRate}_{P1,T12} = \left( \frac{(0.015 - 0.0075)}{500} \right) = 0.000015 \text{ seconds/mile}$$

Note that in some cases, one or two data points used to plot the Best Line actually lies on the Best Line. In these cases, the Best Line rate used is the pessimistic $2/3c$ as defined for the UBM method. This will account for biasing the results of the analysis by erroneously indicating the exact correct location when geolocating a node whose data was used to define the Best Line.

In some cases, the Best Line would result in a negative intercept, which is not allowed. In these cases, the origin point (0,0) was used as an anchor point in conjunction with one other data point to define the Best Line. Figure 7 shows an example using Seattle as the polling node and Boston as the target node. In this case, it was necessary to use the origin (0,0) and the San Jose node to determine the Best Line.
Once the Best Line rate is calculated, the estimated distance from all polling nodes to the target node, circles are drawn around each of the polling nodes. The intersection of the circles provides the multilateration necessary to localize the geographic location of the target node as was shown in the UBM method.

### 3.3.3 Time to Location Heuristic (TTLH)

The TTLH method is unique in that it does not resolve to a distance from the polling node, but instead identifies the node nearest to the target. The TTLH method uses the Euclidean distance as a means to locate the end node that is nearest to an unknown target. The round-trip time collected in the data collection phase will be divided by two.
to estimate the one-way delay between the polling nodes and the end nodes, as well as between the polling nodes and the target node. These values are entered into the Euclidian Distance formula shown below in Equation 9 where \( p \) = number of polling nodes, \( e \) = end nodes, \( t \) = target node, \( x_{ie} \) = time from polling node to end node, and \( x_{it} \) = time from polling node to target node:

\[
d_e = \sqrt{\sum_{i=1}^{p} (x_{ie} - x_{it})^2}
\]  

(9)

Suppose that there are 3 polling nodes, 4 end nodes, and 1 target node. The calculations resulting from the application of the Euclidean Distance formula would be as follows as shown in Equation 10 below:

\[
d_1 = \sqrt{(x_{11} - x_{1t})^2 + (x_{21} - x_{2t})^2 + (x_{31} - x_{3t})^2}
\]

\[
d_2 = \sqrt{(x_{12} - x_{1t})^2 + (x_{22} - x_{2t})^2 + (x_{32} - x_{3t})^2}
\]

\[
d_3 = \sqrt{(x_{13} - x_{1t})^2 + (x_{23} - x_{2t})^2 + (x_{33} - x_{3t})^2}
\]

\[
d_4 = \sqrt{(x_{14} - x_{1t})^2 + (x_{24} - x_{2t})^2 + (x_{34} - x_{3t})^2}
\]

(10)

In the TTLH method, the end node \( (d_e) \) with the lowest magnitude would be identified as the node nearest to the target.

Since TTLH requires at least two polling nodes to solve the Euclidean Distance equation, the number of possible end node combinations is limited. There are eight ways to organize the polling, end, and target nodes from the set of nine possible end or polling nodes as shown below in Table 2. During each iteration of the TTLH, the maximum number of end nodes will be included in the test. This is done to include as many data
points as possible when calculating the results. Two polling nodes, nine end nodes and one target can be permuted in any one of 660 different ways. The eight different possible categories of network architecture and the corresponding number of unique network architectures possible are shown below in Table 2:

### 3.4 Metrics

In this section, the figures of merit used for measuring the accuracy of each of the delay-based IP Geolocation method is presented.

#### 3.4.1 UBM and CBG

Metrics will be gathered for the purpose of comparing the accuracy of UBM to CBG. Since the UBM and CBG methods estimate a distance between the polling node
and the target node, important metrics include the miss distance, the percent of error, and the target overlap area.

The first metric that will be calculated is the miss distance. The miss distance is defined as the difference between the estimated distance to the target and the actual distance to the target as shown in Figure 8 below. For example, suppose that Miami is the polling node and the CBG method estimated the distance to the Hartford target to be 1,914 miles. However, in reality the target is 1,414 miles away. In this case, the resulting miss distance would be calculated as $(1,914 - 1,414) = 500$ miles.

Note that a positive result for miss distance will show that the target location is being underestimated. Both of the UBM and CBG methods are designed to be pessimistic and should never underestimate the distance from the polling node to the target node.
This is important because the area of a circle drawn around a polling node that underestimated the distance to the target would not cover the target. The miss distance will be calculated for each of the twelve polling nodes to all of the eleven targets, for a total of 132 calculations.

The second metric that will be calculate is the percentage of error. The percentage of error is defined as the ratio of the miss distance to the actual distance to the target time one-hundred as shown in Equation 11:

\[
\text{Percent of Error}(\%) = \left( \frac{\text{Miss Distance}}{\text{Actual Distance}} \right) \times 100
\]  
\[
\text{Equation 11}
\]

Using the example from Miami to Hartford again, the miss distance to the target was 500 miles from the polling node but the actual distance is 1,414 miles. Equation 12 shows the result of the calculating the percent of error from Miami to Hartford is 0.3536.

\[
\text{Percent of Error}_{\text{Miami–Hartford}} = \left( \frac{500}{1414} \right) \times 100 = 35.36\%
\]  
\[
\text{Equation 12}
\]

Note that if the miss distance is small, the percentage of error drops. The percentage of error will be calculated for the UBM and CBG methods for each of the 132 cases discussed above considering each node as a polling node and the remaining nodes as target nodes.

The third metric that will be calculated is the area of overlap. The area of overlap is calculated by integrating the area that is overlapped by the intersecting circles surrounding the polling nodes as shown in Equation 13 below:

\[
\text{Area} = \int_{\text{MinLat}}^{\text{MaxLat}} \int_{\text{MinLong}}^{\text{MaxLong}} f_{\text{UBM}}(x, y) \, dy \, dx
\]  
\[
\text{Equation 13}
\]
Since the area of overlap is not easily represented as a continuous function due to its irregular shape, a computer program was written in the “C” programming language to calculate the discrete approximation to the area (see Appendix B). A two dimensional grid is created and laid on top of the geographic map. The grid has 1 mile resolution in both the x and y dimensions. Step functions are created that serve to locate the circles surrounding each polling node and return True if a given point is within the circle, and False otherwise. The step functions are logically ANDed together to determine if for a given x and y coordinate, the circles overlap. The area is of overlap is calculated by sweeping across the x and y dimensions and summing the number of points that overlap. Equation 14 below shows the equivalent area calculation:

\[
Area = \sum_{MinLat}^{MaxLat} \sum_{MinLong}^{MaxLong} f_{CIRCLE_1}(x, y) \cap f_{CIRCLE_2}(x, y) \cap f_{CIRCLE_3}(x, y) \quad (14)
\]

The overlap area was found 12 times, once for each of the targets when all of the polling nodes were utilized. Figure 9 shows an example of what the area of overlap might look like for a target with five polling nodes.
3.4.2 TTLH Metrics

The TTLH strives to find the nearest end node to the targets location. The UBM and CBG methods return the targets area, but the TTLH returns a node. Comparing the resulting area from UBM and CBG to the resulting node in TTLH is like comparing apples to oranges. The goals of the TTLH are different from the goals of UBM and CBG. Therefore, the metrics collected from the TTLH results do not attempt to directly compare the accuracy against the accuracy of UBM and CBG, rather the TTLH metrics will show the likelihood of the nearest known-node being selected.
The results of TTLH will be considered a success if the nearest-known end node is correctly identified. It is a failure if any node other than the nearest node is identified as the nearest node. The accuracy of the TTLH is limited by the number and the location of end nodes. The results have a finite number of possible results for the nearest known node. The TTLH examples were considered to be a success when the result showed the nearest-known network node to be the same nearest-known node physically. A computer program was used that could calculate the Euclidean distances for all combinations of the TTLH. The program stored and counted the number of successful and failed trials for the TTLH calculations.

The Euclidean distances for every possible combination of each iteration were computed with the use of a computer program. The program stored the results of each iteration. It did this by producing files for the successful and the unsuccessful trials. The Number of trials in those files were counted to find the accuracy rates. Those successes and failures were analyzed to see if the numbers and locations of the end and polling nodes have an effect on the accuracy of the results. The TTLH methodology was tested by calculating the results a total of 24,288 times, one for every possible iteration of the project as shown in Table 2.

3.5 Assumptions

A real-world application of the delay-based IP Geolocation methods discussed in this thesis would require some assumptions to be reported along with any analysis using these methods. For example, it is assumed that the target node has not tried to elude location detection. An evasive target employing any number of methods could invalidate
the results of the analysis by corrupting the delay measurement. For example, the target computer can add a fixed delay or vary the fixed delay using a distribution and parameters designed to confuse the analysis. This technique could be built into any piece of network equipment such as a router or a switch.

3.6 Summary

This chapter introduced the research design, the data collection process, and how data will be analyzed to answer the research questions. A discussion of how the network architectures will be permuted from the basic network map was presented. Examples of the application of the UBM, CBG, and TTLH geolocation methods was provided to give the reader insight into the analysis required to answer the research questions. Metrics were defined in an effort to measure the accuracy of the delay-based IP Geolocation methods.
4. Results and Analysis

In this chapter, the research data collection, application of the delay-based IP Geolocation methods, metrics calculation, and an analysis of the results are presented. Based upon the findings of the research, a novel hybrid methodology is proposed that can be used to improve the accuracy of delay-based IP Geolocation methods.

4.1 Data Collection

The network architecture presented in chapter three was modeled using OPNET version 12.0. With OPNET, a command script was written which allow for automated data collection. The script resulted in each of the 12 nodes in the architecture to PING each of the remaining 11 nodes every 30 minutes. The results from the PINGs over a 24 hour time period were written into a file. While a single PING would be sufficient, the researcher wanted to verify that the delay times did not vary when using ideal network configurations. The model was simulated on Dell Precision Workstation 690N - 1KW Dual Core Intel Xeon® Processor running at 3.0GHz with a 4MB L2 cache and 4 GB of system RAM. Upon completion of the simulation, the collected delay measurements were compared and the ideal simulation showed less than 0.01% difference in delay measurements across the 24 hour simulated time interval.

The collected delay measurements were entered into an Excel spreadsheet to facilitate post-processing and save in a comma delimited text file. Subsequently, the delay measurement file was loaded into a “C” computer program where it was stored as a 12 x 12 matrix of floating point number for use when calculating the results using each of
the geolocation methodologies under test. The delay data collected for this research project is shown in Table 3.

</table>
4.1 Upper-Bound Multilateration

The first method analyzed based upon the simulation results was Upper-Bound Multilateration (UBM). UBM finds an upper bound of the distance to a destination node by using 2/3 speed of light for a rate of transmission. The Round-trip Time (RTT) from each polling node was first divided in half to estimate the one-way transmission delay, that delay measurement was then multiplied by 2/3 speed of light to find the upper bound for the target node. In this research project, each polling node used the eleven other nodes as targets. The resulting distances from each node to all of the other nodes are shown in Table 4.

Note that the driving distances were used as the actual distances between targets. As discussed in section 2.6, network traffic flows along fiber-optic lines that are primarily buried along right-of-ways which typically parallel major highways. For this reason, the driving distances between nodes are shown Table 5 were used as the physical distance between nodes.

The first metric used to measure the accuracy of the UBM method, the miss distance, is used as a sanity check because it determines if the use of the 2/3 rate was too slow. The miss distance metric was calculated by subtracting the actual distance between cites from the distance that UBM had estimated it to be. If UBM underestimated the upper bound, the result of subtracting the actual distance from the estimated distance would be a negative number. The results were positive for all 132 iterations of the project. The number of miles that were overestimated to each node are shown in Table 6.

4.1.1 UBM Results

There were three metrics gathered for UBM to quantify the accuracy of the UBM estimated distance from a polling node to a target node: the miss distance, the error rate, and the area of the overlapping circles.

Miss distance was calculated by subtracting the actual distance from the UBM estimated distance. All of the miss distance figures were positive, which indicates that UBM never underestimated the distance. The mean miss distance for all 132 iterations was 770.69 miles. The maximum miss distance was 2,061.86 miles and the minimum miss distance was 16.75 miles when using the UBM method. The miss distance for all 132 iterations of the UBM is shown in Table 6.

The percentage of error was calculated by taking the miss distance and dividing by the actual distance. The mean error percentage for all of the 132 iterations was 99.6%. On average, this methodology is missing the target by a factor of 2. However, the variance was large with some estimations having error rate of 1% while others were greater than 700%. The error rates for all 132 iterations of the UBM is shown in Table 8.

The area of overlap was calculated twelve times, once for each target. The area was calculated by integrating the overlapped circles using all other eleven nodes as polling nodes. The results for all of the targets showed a mean area of 1,315,534 square miles. To put the size of that area into perspective, the approximate size of the state of Texas is 261,797 square miles [28]. The smallest area of overlap was 117,315 square miles, and the largest area found by UBM was 2,465,820 square miles. Table 7 shows the area of overlap for each of the twelve targets. Figure 10 shows the resulting area for
the target of Hartford (T2) when all of the other nodes were utilized. Note that some of the upper-bounds from a couple of end nodes are so large that they do not appear on the map.

4.2 Constraint-Based Geolocation

An analysis of the Constraint Based Geolocation results showed that it was better than UBM for every metric collected. This was an expected result because CBG uses attempts to use a more accurate rate of transmission than the UBM method. The rate of transmission is found by first determining a bestline from each polling node. Table 11 shows the equation of the bestline ($y = mx + b$) that was used from each polling node to each target node.

4.2.1 CBG Results

Miss distance was calculated by subtracting the actual distance from the CBG estimated distance. All of the miss distance figures were positive, just like the UBM results, proving that CBG never underestimated the distance from the polling node to target. That means that the target was always located in the overlapping area of the circles. The mean miss distance for all 132 iterations was 661.11 miles, slightly better than the UBM results. The maximum miss distance was 3,459 miles and the minimum miss distance was 10 miles when using the CBG method. The miss distance from each polling node to all of the targets is shown in Table 9.

To find the percentage of error, the estimated distance was divided by the actual distance. The mean error of the 132 iterations was 78.4%. The maximum percentage of error was 1014.37% and the minimum percentage of error was 1.43% when using the CBG method. Again, the maximum error rate was from the San Jose polling node to the Los Angeles target node. The error rates all 132 iterations are shown in Table 10.
The third metric collected from the resulting UBM data was the area of overlap. As in UBM, the area was calculated twelve times, once for each target. The results for all of the targets showed a mean area of 687,913 square miles. The most accurate target resulted in an area of 25,785 square miles, the largest area found by CBG was 1,668,759 square miles. The individual areas for each target are shown in Table 12. Figure 12 shows the resulting area for the target of Hartford (T2) when all of the nodes were utilized. CBG proved to be more accurate than UBM. The effectiveness of each method was calculated three separate ways. CBG was the more accurate method in all three cases.

The maximum miss distance in the CBG method was from polling node in San Jose to the target node of Los Angeles. As seen in figure 4, the network path that a message would have to take in this simulation would have required the message to travel from San Jose through routers in Portland, Las Vegas, then Phoenix before it could reach the target nodes location in Los Angeles. The network topology forced an indirect route to the target. The network topology also had an effect on the rate used for the bestline. As discussed in section 3.5.2, The San Jose polling node required the use of the data point (0,0) when drawing the bestline in order to keep all results positive. Figure 11 shows the bestline for the polling node in San Jose. The one data point used to find the bestline is located in Seattle. This was because the network topology allowed for a direct route through one router to the node in Seattle, but it did not allow for any direct routes to any other nodes.
Figure 11 demonstrates an unexpected advantage of the CBG method. By charting the delay vs. the distance for all of the end nodes, the outlier for one case can be seen. Even with the outlier included the upper-bounds are not underestimated. The CBG method defaults to a pessimistic upper-bound and the target area is included in the area. CBG defaults to include the target in a large area of overlap instead of underestimating the target and not including it in the area. The success of the CBG in this project could be slightly improved by excluding the outlier in the overall calculations. In order to accurately compare the CBG method with the UBM method all 132 calculations were included. Even with an outlier clearly visible and included, CBG always resulted in more accurate data.

4.3 TTLH

The TTLH methodology was used to identify the nearest node using the collected delay measurements. A computer program enumerated all possible combinations of target nodes, polling nodes, and end nodes. In each trial, the maximum numbers of end nodes were used. The results show a trend in which the accuracy of the data increases slightly when the number of polling nodes increases. In this research, the number of end nodes dropped as the polling nodes increased. When nine polling nodes were used, TTLH only had two end nodes to choose from as the nearest node. The results are shown in Figure 13.
Figure 13. TTLH Scatterplot of Polling Nodes and Accuracy
A couple of interesting trends were discovered when the results were analyzed. The TTLH failed to identify the nearest-known node to Boston (T1) only when the New York (T8) and Hartford (T2) nodes were used as polling nodes, not as end nodes. When the target node Boston had a choice of either Hartford or New York as an end node, TTLH was 100% successful.

The three nodes that were most successful overall were the nodes located in Boston (T1), Hartford (T2), and New York (T8). No other three nodes in the polling set have nodes that are located closer to each other than these three. Most of the failures to identify the nearest node to any of these three nodes happen when neither of the other two nodes are used as end nodes. The accuracy rates from each of the eight ways to organize the TTLH test are shown in the Tables 14 - 21:

4.3.1 TTLH Results

The results from all 24,288 combinations correctly identified the nearest-known node at a rate of 80.15%. The nodes with the lowest accuracy rates were located on the West coast. TTLH uses the Euclidean distance formula to measure network distance. The network distance is assumed to correspond to a physical distance. An analysis of the simulated network topology revealed that the network distances did not always directly correspond to a short physical distance. In most cases, the nearest-known node using network measurements will also be the nearest known-node physically. The West coast nodes fail more often than the other nodes because of a flaw in the network design. The design on the West coast does not allow for the shortest network distance to be the shortest physical distance in all cases.

When analyzing the examples that failed to correctly identify the nearest node, a couple of trends were noticed. The TTLH results failed more often when the actual
nearest nodes were utilized as polling nodes. The correct nearest node was identified more often when the actual nearest node was used as an end node.

To test the assumption that the network topology can influence the results of TTLH, a thirteenth node was introduced into the project. This node was connected so that the closest network node would not be the geographically closest node. The thirteenth node was located in Birmingham. Its closest node on the network was the Jacksonville node, but the shortest physical node was in New Orleans. As expected, TTLH consistently identified the nearest-known node as the nearest node on the network. Since the nearest geographic node was not correctly identified those results were considered incorrect. When the Birmingham node was introduced, the overall accuracy of TTLH dropped from 80.15% down to 64.07%. Having an understanding of the network topology will help the researcher know when TTLH is providing the nearest-known physical node incorrectly.
4.4 Hybrid Methodology

The results of the TTLH show that the positioning of nodes has an effect on the results. An objective of this research was to determine if the accuracy of the delay-based IP Geolocation methods could be improved. For this reason, a hybrid methodology is proposed which uses a combination of UBM, CBG and TTLH when trying to geolocate a device by only using delay measurements. The researcher used the results of the UBM and CBG examples to choose the location of the end nodes and polling nodes used for the TTLH example. The TTLH examples show the best results when it has end nodes located closer to the target than polling nodes. UBM and CBG can be used to give an approximate location of the target. This was calculated for all twelve targets, but for the ease of discussion one target was selected to show how this hybrid methodology will work.

The first step in this methodology would be to use UBM to determine the wide area a target is located. This is done by finding one-way delay times to a target node and estimating the upper bound by using 2/3 speed of light for rate. Once those distances are known they can be drawn to a map and triangulation can be used to determine the approximate area where the target is located. This was accomplished for each of the targets. An example from the target located in Hartford is shown in Figure 10. That resulting area immediately tells us that the target node is located somewhere in the northern part of the east coast.

The next step used constraint-based geolocation to find a more accurate rate of transmission. The bestline was determined from each polling node. The delay times
were plotted on the bestline, and x intercepts were used to determine the distance from
the polling node to the target. Those distances were then drawn on a map.
Multilateration gives an area of overlap that contains the target.

Now that two areas have been found for the location of the target, the CBG results
can be compared with the UBM results to determine if they agree on the location of the
target. Then TTLH can be accomplished by first selecting end nodes that are located in
or near the area of overlap. In this example, end node 1 and end node 8 are the only two
end nodes that are located close to the shaded area from the CBG. TTLH was conducted
using the combination of two end nodes and nine polling nodes. That combination was
chosen because only two end nodes are located near the shaded area. The greatest
number of polling nodes available was nine. The final step was to find the Euclidean
distances of the two selected end nodes with the maximum number of available polling
nodes.

4.4.1 Hybrid Methodology Results

End node 1 resulted in the lowest Euclidean distance, so it was determined that
the target node is located closest to that node. The target node selected for this example,
is located in Hartford. The end node that was selected as the nearest node is located in
Boston. The results were correct; Boston is the nearest known node to Hartford in this
simulation.

That methodology was repeated for the other eleven nodes in this example. Using
the hybrid methodology, end nodes were selected for TTLH based on their proximity to
the overlapping areas from constraint-based geolocation. In eleven of the twelve cases,
TTLH returned the correct nearest node when the end nodes were located closest to the target. The one case that did not identify the nearest geographic node did correctly identify the nearest network node. That one case where the hybrid methodology failed was when Seattle was the target node. The hybrid results claimed Los Angeles to be the nearest node, but San Jose is in fact the correct nearest node. A flaw in the network design is to blame for this result; the network paths to Los Angeles are closer in length to the paths to Seattle than the network paths to the correct nearest node San Jose. The underlying assumption to TTLH is that the network distance corresponds to the physical distance. It was discussed earlier in this paper that networks often follow shortest routes to the destination but is not always the case.

Using the hybrid methodology, the success rate of TTLH improved. The shotgun approach to TTLH yielded an overall success rate of 80.15%, but when the hybrid methodology was used the success rate increased to 91.66%.

4.5 Summary

The data collected and presented in this chapter showed that the CBG is a more accurate than the UBM method for geolocation. Both of these methodologies showed that the location of a target node can be found to some levels of granularity. The TTLH results showed that the positioning of the nodes has an effect on the results of the test. The accuracy rates of TTLH improve when an end node is closely located to the target node. Based on the results, a hybrid methodology was presented and tested. The hybrid method uses the results of the CBG method to select end nodes that are most likely to be located close to the target. When the hybrid methodology was tested, the accuracy rates of finding the nearest-known node improved.
5. Conclusions and Recommendations

The ability to determine the geographic location of a node on the Internet based upon its Internet Protocol address is an essential tool for many commercial and military applications. IP Geolocation can also be used to add another layer of protection. When authenticating users, locate the source of connection attempts to sensitive information assets, and to locate unmapped nodes. While the current methods used for IP Geolocation are not exact, in many cases they provide an acceptable estimate of the physical location of the IP address.

Geolocation can be accomplished through a number of methodologies. Those methodologies fall into three categories. 1) methods that store location information in databases, 2) methods that use information leakage to find the target locations, and 3) methods that calculate the location based upon delay measurements. This project focused on the third method, because collecting delay measurements give complete control of the accuracy of the data to the researcher. The information used in the other methods is easily corruptible, either purposely or inadvertently. The methods that were analyzed in a simulation environment for this project found the location of the target node through the use of multilateration and the nearest known node.

In this thesis, various methods for IP Geolocation were introduced, a brief understanding of their operation was provided, and the research investigation of delay-based methods was discussed. Analysis of the collected results show that distance estimations could be made from delay measurements. The UBM and CBG methods use delay measurements to determine the upper bound on the distance to the target location.
Replicating these geolocation methods found that they can be used to determine the geographic region of a target to some granularity. This project also showed that CBG is a more accurate method than UBM.

The TTLH was selected as a nearest-known node methodology to replicate. This methodology does not return the area of the target, but rather the known node that is located closest to the target. Since the calculations are all done with network data, an assumption of the nearest known node methodologies is that the nearest known node on the network is also the nearest known node physically. This assumption was tested by adding a node on the network where the nearest network node was not the nearest physical node. The accuracy rates of TTLH dropped dramatically after that node was included. The network infrastructure can cause false geolocation results.

A hybrid methodology was proposed that uses the results of multilateration geolocation to select nodes to be used for nearest-known node experiments. Perhaps the most important finding of this project was that the results from the nearest-known node experiments showed that the positioning of the end nodes in relation to the target had an effect on the accuracy of the results. The hybrid methodology first finds the area that a target is located by conducting the multilateration methodologies. Then it selects end nodes that are located in or close to that area. That hybrid methodology was tested and it was found that the accuracy of the finding the nearest-known node was increased.

### 5.1 Summary of Results

The UBM results were promising. At first glance they do not look very accurate. On average the estimations were overshooting the target by a factor of two, and the
resulting mean area of overlap for all targets was 1,315,534 square miles which is five times larger than the state of Texas. Looking closely at the results showed many target locations that were much smaller than the mean and when those area were plotted, much of the area fell over the ocean. The resulting area for each target always would exclude a portion of the country. The very pessimistic constant rate of 2/3 speed of light did reveal the target’s location to some granularity. That can be used in the overall geolocation effort that should include more than one methodology.

The CBG results were more accurate than the UBM results. This was not unexpected because the CBG uses known network nodes to find a more accurate rate of transmission than the UBM. The mean area for all targets in CBG was about half the size of the UBM results at 687,913 square miles. The most interesting finding from analyzing the CBG data was that the method strives to ensure the target’s location is included in the resulting area. The bestline is defaults to a pessimistic rate by using the line that is close to but below all data points. The bestline could use a more accurate rate by using the mean of all the data points, but that would then underestimate the distance to the target, thus not including the target in the overlapping area. By defaulting to pessimistic rates CBG method sacrifices accuracy to ensure the targets location is including in the resulting area.

The TTLH data also showed some interesting findings. The overall accuracy rate of 80.15% gave plenty of examples to study to find when the method would fail to return the closest physical node to the target node. Although the closest physical node was only determined on average 4 out of 5 times, the closest network node was always returned correctly. The TTLH assumes that the closest network node is also the closest physical
node. Most often that is the case. The need for some knowledge of the network infrastructure for the target is beneficial to someone using TTLH for geolocation.

The TTLH results led to the development of a new hybrid methodology. TTLH was correctly returning the nearest network node, but that was not always the nearest physical node. It also was more accurate when the target had end nodes closer to it than polling nodes. By using the resulting areas from UBM and CBG one can select end nodes that are geographically close to the target. Then the TTLH method is conducted with those selected end nodes. This hybrid method was conducted for all twelve targets used in this simulation. The correct nearest node was returned eleven times for an accuracy rate of 91.66%. The one target node that was not correctly identified was the Seattle node. Having an idea of the network topology made it easy to see why San Jose was not selected as the nearest node to Seattle. The node in Los Angeles was closer on the network to Seattle than San Jose. Knowing the network infrastructure can help determine when TTLH is returning incorrect results. Using the hybrid methodology that was introduced here in section 4.4 can help someone achieve more accurate geolocation results than when a single methodology is employed.

5.2 Significance of Research

The significance of the research is that the accuracy of delay-based IP Geolocation can be improved when combining methods together into a hybrid methodology. The results will enable the reader to apply the new hybrid methodology and improve real-world applications of delay-based IP Geolocation.
5.3 Limitations

This project was limited by the size of the network in the simulation. A more robust network would have allowed more network paths to travel in the shortest geographic distances. A larger network would also have allowed for more end nodes, polling nodes and target nodes to add to the complexity of the examples.

The number of nodes used in this data was twelve. This relatively small number limited the complexity of calculations that could be completed. As polling nodes are increased, multilateration increases the number of circles that are determining the area of the target. When a polling node is added that area has a possibility of shrinking.

TTLH was conducted using the maximum number of polling nodes for each test. As the number of polling nodes increased, the number of end nodes decreased. This may have limited the accuracy of TTLH because when nine polling nodes were used, it was a 50% of being right.

5.4 Future Research

The possibilities of future research are plentiful. This project introduced a methodology that would be interesting to test in a real world network. Combining the Upper-Bound Multilateration, Constraint- Based Geolocation, and TTLH into a real life experiment could yield interesting results. This could be done by replicating the hybrid methodology introduced here. Other geolocation methods such as whois could be used to increase the number and find the location of end nodes used in the experiment.

It would also be beneficial to change the scale of this research project to a smaller scale such as the size of a state or a city. The granularity of the accuracy of the results is
dependant upon the numbers and the locations of the end nodes. Improving the granularity of the geolocation results would be a great benefit. Another possible area of research would be to translate these methods to a real life experiment. The TTLH could be tested in a MAN by using target, end, and polling nodes located around a metropolitan area that are under the control of the researcher.

It would be interesting to study the TTLH methodology to find at what point adding polling nodes does not improve the accuracy of the data. Further, it is desired to conduct a detailed analysis of the impact of varying line speeds to selected nodes with the goal of developing a correction factor in the Euclidian distance formula.

}
```

### Explanation

The provided code snippet is a function `printMinimumDistances` that takes several parameters including arrays and indices to print minimum Euclidean and driving distances. The function is designed to compare the minimum Euclidean distance with the minimum driving distance and print out relevant information if the minimum Euclidean distance does not match the minimum driving distance. It includes print statements for the target node, total polling nodes, polling nodes, total end nodes, end nodes, minimum Euclidean distance, and minimum driving distance.

The function first checks if the `minimumindex` is greater than or equal to 0. If it is, it prints an error message indicating that the minimum Euclidean distance does not match the minimum driving distance, along with additional information such as the target node, total polling nodes, polling nodes, total end nodes, end nodes, and Euclidean and driving distances for the minimum values.

The function then prints the minimum Euclidean and driving distances using formatted strings, where the target node and minimum values are printed with specific indices and values.
if (minimumindex == minimumCFindex) {
    printf("**** CORRECT *** Minimum Euclidian Matches \n")
    break;
}

14. ABSTRACT
Internet Protocol Geolocation (IP Geolocation), the process of determining the approximate geographic location of an IP addressable node, has proven useful in a wide variety of commercial applications. Commercial applications of IP Geolocation include market research, redirection for performance enhancement, restricting content, and combating fraud. The potential for military applications include securing remote access via geographic authentication, intelligence collection, and cyber attack attribution.

IP Geolocation methods can be divided into three basic categories based upon which information is used to determine the geographic location of the given IP address: 1) Information contained in databases, 2) information that is leaked during connections with the IP of interest, and 3) network-based routing and timing information. This thesis focused upon an analysis in the third category: delay-based methods for IP Geolocation. Specifically, a comparative analysis of three existing delay-based IP Geolocation methods: Upper-bound Multilateration (UBM), Constraint Based Geolocation (CBG), and Time to Location Heuristic (TTLH) is conducted using a simulated network. Based upon analysis of the results, a new hybrid methodology is proposed to improve the accuracy when conducting IP Geolocation. Simulations of the new hybrid methodology show that the hybrid methodology is superior to all existing delay-based methods for IP Geolocation.
